Different mechanisms of absorption enhancement for these permeation enhancers have been proposed. Most permeation enhancers are thought to disrupt the lipid bilayer, which increases membrane fluidity. Some enhancers (nonionic and presumably ionic surfactants) may solubilize and extract lipids (92). Bile salts enhance absorption, stabilize enzyme-labile drugs, and potentially inhibit proteolytic degradation and aggregation of therapeutic proteins by formation of micelles (92). Permeation enhancers, which open tight junctions, are of little benefit in oral mucosal drug delivery because tight junctions are uncommon in these tissues. Structure-/absorption enhancement activity relationships have not been completely characterized for permeation enhancers (Table 3). However, for surfactants, the structure of the polar head groups strongly influences the permeability. For example, it has been reported that for surfactants, absorption enhancement was greatest for ether-based surfactants rather than for esters with similar structure (92).

SUMMARY

In recent years, there has been explosive growth in our understanding of the mechanisms associated with the absorption of drugs, especially of therapeutic peptides and

proteins. Scientists from a variety of disciplines continue to elucidate the variables associated with the optimal formulation and delivery of drugs via the oral mucosa. A greater understanding of the para- and transcellular route of drug absorption, proteolytic enzyme activity that may potentially degrade therapeutic peptides, and simultaneous degradation of compounds during the mucosal transport process is essential to the development of buccal delivery systems. Moreover, methods to increase drug flux (e.g., use of permeation enhancers) without associated toxicity, strategies to inactivate proteolytic enzymes, and innovative approaches with regard to controlled drug-delivery and mucoadhesive dosage forms will all improve the delivery of drug substances via the oral cavity.

PEDIATRIC DOSING AND DOSAGE FORMS

Rosalie Sagraves

University of Illinois at Chicago, Chicago, Illinois, U.S.A.

INTRODUCTION

The administration of medications to pediatric patients is in many ways difficult because health care providers and parents are faced with many challenges not experienced, or experienced to a lesser degree, than when medications are prescribed for and taken by adults. First, less information is available about the use of most medications for pediatric patients. In fact only about 20% of drugs marketed in the United States have labeling for pediatric use (1). Milap Nahata, in a 1999 article on pediatric drug formulations, stated that "only five of the 80 drugs most commonly used in newborns, and infants are approved for pediatric use" (1). Second, many drugs that are used for some pediatric patients are not in appropriate dosage forms for use by children. This includes even some medications approved for use in pediatric patients. These issues have resulted in many questions that need to be answered about drug administration to pediatric patients. For example, is the drug approved for use in pediatric patients and in what age groups? If not approved, is there scientific information that enables us to determine whether the drug is safe and effective for pediatric patients of various ages? If the drug is available commercially for pediatric use, what dose should be administered and how frequently? What route should be used for administration, and what dosage form selected? If the drug is not available in an appropriate dosage form for childhood use, can it be prepared extemporaneously? Is there stability studies, palatability tests, clinical data in children, etc. that pertain to the extemporaneous formulation? How should the drug be monitored for effectiveness as well as for adverse effects? Information determined in adult medication studies may not be applicable to pediatric patients because of pharmacokinetic and pharmacodynamic differences as well as differences in disease states for which a particular drug might be used. Many questions about the use of particular drugs in various age groups of pediatric patients can only be answered through well-designed, randomized controlled studies in pediatric patients who need certain medications for particular health problems.

In 1997, the Food and Drug Administration (FDA) proposed new regulations for how pharmaceutical manufacturers would access safety and efficacy of certain new drugs that could have pediatric indications (1, 2). Thereafter, the FDA and the American Association of Pharmaceutical Scientists (AAPS) held a conference with academicians, pharmaceutical industry representatives, and U.S. Pharmacopeia (USP) representatives to discuss these proposed FDA regulations.

The FDA Modernization Act (FDAMA) of 1997 contains within it financial incentives for the development and marketing of drugs that could be used for pediatric patients (3). Some of these incentives include an extension of 6 months on market exclusivity and waiving fees for supplemental applications needed for receiving the approval of drugs for pediatric use that are already approved for adult use. In addition, the FDA published a list of drugs approved in adults for which additional pediatric data may produce health benefits for pediatric patients (4). For drugs on this list, FDA may ask a pharmaceutical manufacturer why it has not sought approval of a particular drug for pediatric use. So far there has not been much advancement in this area. This may be due to the wait for final approval of FDAMA.

Various medical and pharmacy organizations have worked hard throughout the years in their efforts to better educate children, parents, educators, and health care providers about the medications and their appropriate use. Indeed, individuals who help care for children may not be adequately trained to educate children about medications that they need to use. Therefore in June 2000, the USP started the development of three target initiatives: principles for educating children about their medications, guidelines for developing and evaluating information for children, and developing specific curricular information in a modular format (5). The USP position about educating children about medications may be found on their website (www.usp.org). The following information pieces have been developed by the USP (5):

- *Guide to Developing and Evaluating Medicine Education Programs and Materials for Children and*

Adolescents (joint publication of the American Health Association and USP)

- *A Kid's Guide to Asking Questions about Medicines*
- *Teaching Kids about Medicines*
- *Talking to Children about Their Medicines* (pamphlet developed jointly by Pfizer and USP to be disseminated to pediatricians and children's families)
- An Annotated Bibliography of Research and Programs Relating to Children and Medications

The USP has started working with the National Center for Health Education in New York to develop educational materials that can help school systems nationwide to know more about medications that students may need to take. The USP also adopted the following resolution to address the work that needs to be done in the area of health education (5):

Facilitate and contribute to the development of a rational school medicines policy, including guidelines for student, faculty, and staff medicine education, for acquisition, transport, storage, administration, use, and disposal of medicines; for protection of privacy; and for record-keeping in primary and secondary schools. Initiatives should be undertaken in collaboration with appropriate partners.

The USP has been working with the National Institute of Child Health and Human Development (NICHD) to develop a list of drugs for which more pediatric information is needed to insure proper use in children. The USP is also evaluating similarities and differences among neonates, children, and adults that may affect medication dosing and which might help in the appropriate

labeling of medicines for pediatric use. The USP is reviewing the literature and developing tables for drugs, using evidence-based information. USP members can find this information by contacting Joyce Weaver (jpw@usp.org).

This overview of pediatric dosing and dosage forms covers issues that pediatric health care providers face daily, such as age-related drug pharmacokinetic and pharmacodynamic changes that occur secondarily to physiologic changes in maturing neonates, infants, children, and adolescents that can affect drug absorption from various routes of administration as well as drug distribution, metabolism, and elimination. To be more knowledgeable about pharmacokinetic changes, therapeutic drug monitoring (TDM) must be undertaken for drugs with narrow therapeutic indexes and for those for which pharmacodynamic data (i.e., pharmacologic response that correlates to the drug concentration at the receptor site) correlates with pharmacokinetic information. Also addressed will be drug administration by various routes including intravenous (i.v.), oral (p.o.), intramuscular (i.m.), subcutaneous (s.c.), percutaneous, rectal, otic, nasal, ophthalmic, and inhalation. Another issue discussed is product selection for pediatric patients.

To better understand changes in drug disposition, the pediatric population needs to be categorized into various groups (Table 1) because children vary markedly in their absorption, distribution, metabolism, and elimination of medications. This occurs because neonates, infants, children, adolescents, and adults have different body compositions (i.e., as to their percentages of body water and fat) and have their body organs in different stages of development.

Table 1 Pediatric age groups terminology

Terms	Definition
Gestational age	Time from the mother's last menstrual period to the time the baby is born; at birth, a Dubowitz score in weeks gestational age is assigned, based on the physical examination of the newborn
Postnatal age	Age since birth
Postconceptional age	Age since conception, i.e., gestational plus postnatal age
Neonate	First 4 weeks or first month of life
Premature neonates	Born at less than 37-weeks gestation
Fullterm neonates	Born between 37- and 42-weeks gestation
Postterm neonates	Born after 42-weeks gestation
Infant	1 month to 1 year of age
Child	1–12 years of age
Adolescent	12–18 years of age

PEDIATRIC PHARMACOKINETICS AND PHARMACODYNAMICS

Effect of Developmental Physiologic Changes on Pharmacokinetics and Pharmacodynamics of Drugs

Rational pediatric pharmacotherapy is primarily based on the knowledge about a particular drug, including its pharmacokinetics and pharmacodynamics, that may be modified by physiologic maturation of the child from birth through adolescence. Physiologic changes that occur can affect drug absorption, distribution, metabolism, and elimination. The most dramatic changes occur during the neonatal period.

Oral Absorption

Drug absorption from the gastrointestinal (GI) tract is dependent on patient factors, physicochemical properties of the orally administered drug, and the drug formulation. Patient factors that affect GI absorption include absorptive surface area, maturation of the mucosal membrane, gastric and duodenal pH, gastric emptying time, GI motility, enzyme activity, bacterial colonization of the GI tract, and dietary intake, including the specific gastric content status at the time when a medication is ingested (6–8). Patient factors are influenced by rapid maturational changes that occur throughout early childhood, but which occur primarily during the first few months of life.

Most drugs are absorbed across the GI tract by passive diffusion, but a variety of drug physicochemical factors influence the extent of absorption. These factors include molecular weight, lipid solubility, ionization as well as disintegration and dissolution rates (7). In addition, drug absorption may be dependent on the dosage form selected (e.g., a liquid, a tablet that may need to be crushed, or a sustained-release product), and the particular brand selected. For timed-release preparations, the release characteristics must also be taken into consideration.

Gastric pH

When examining patient-specific factors such as gastric pH, which affect oral absorption, it should be noted that infants born vaginally who are at least 32-weeks gestation, usually have gastric pHs between 6 and 8 at birth (7, 8). Gastric pH then falls rapidly within a few hours after delivery to a pH of less than 3 (7, 8). The initial gastric pH is alkaline compared to that of adults and results from the presence of amniotic fluid in the infant's stomach (9, 10). Thereafter, gastric pH remains acidic until approximately day 10, then a nadir in acid production occurs between

days 10 and 30 of life. Then gastric acid production begins to increase, but gastric pH and maximal gastric output may not mirror that of adults on a per kilogram basis until after the neonatal period (7).

Gastric emptying and gastrointestinal motility

Gastric emptying time in neonates, especially those less than 24 h of age, may be variable (7). It may not reach adult levels until 6–8 months of age and may be associated with diet (11, 12). Gastrointestinal transit time may be prolonged and peristaltic activity unpredictable in young infants (8, 13); both appear affected by the feeding (13). Lebenthal and colleagues noted that breast-fed infants, older than 45 days of age, had gastric transit times longer than 10 h while formula-fed infants had transit times less than 10 h (14). It should also be noted that young infants have a propensity to reflux their gastric contents because of GI immaturity. All these factors affect the extent to which a drug may be absorbed.

Enzyme activity and microflora in the gastrointestinal tract

Pancreatic enzyme activity may be low at birth, but enzymes such as amylase, lipase, and trypsin develop to adult levels within the first year of life (15). Premature infants appear to have lower amylase levels than do full-term infants. Low concentrations of pancreatic enzymes may be the reason why newborns have a decreased ability to cleave prodrug esters such as chloramphenicol palmitate (7). Lipid-soluble drugs may not be well absorbed by neonates because of low lipase concentrations and bile acid pool (8).

More information is needed about the microflora of the GI tract and its effect on drug absorption. In addition, the effects of various diets and antibiotic use can alter the microflora of the GI tract (7).

Absorptive surface area

The surface area of the small intestine in young infants is proportionately greater than in adults. This physiologic difference may allow for increased drug absorption from the GI tract.

Intramuscular Absorption

When a child is unable to take a medication orally or the drug is unavailable for oral use, there may be a need to administer a drug parenterally by either the i.v. or i.m. route. Of these, the latter may be less desirable because of pain, irritation, and decreased drug delivery as compared to i.v. administration. Drug absorption after i.m. administration depends on various physicochemical and

patient factors. Physicochemical factors to be considered include lipid or water solubility, drug concentration, and surface area. When addressing drug solubility, it should be noted that lipophilic drugs readily diffuse through the capillary walls of endothelial cells whereas water-soluble drugs diffuse at fairly rapid rates from interstitial fluid to plasma via pores in capillary membranes (16). A lipid-soluble drug may be more rapidly absorbed i.m., but a water-soluble drug may be more desirable because the drug must be stable in an aqueous solution until administered. After administration, the drug must then be water soluble at physiologic pH until absorption occurs (16).

Drug absorption may be dependent on concentration, but available data do not allow us to determine whether an increased or decreased drug concentration results in better absorption. An increase in the osmolality of a pharmaceutical preparation secondary to the addition of another substance such as an excipient may decrease or slow down i.m. adsorption (16). Absorption occurs more rapidly when diffusion involves a large area of muscle or the drug spreads over a large muscle mass. The massaging of an injection site after i.m. administration increases the rate of absorption (16).

A physiologic determination of i.m. drug absorption is dependent on the adequacy of blood flow to muscle groups used for drug administration. Absorption rates differ at injection sites because blood flow varies among different muscle groups. For example, the absorption of a drug-administered i.m. in the deltoid muscle is faster than from the vastus lateralis that, in turn, is more rapid than from the gluteus (16, 17). This occurs because blood flow to the deltoid muscle is 7% higher than to vastus lateralis and 17% higher than to gluteal muscle groups (18). Physiologic conditions that reduce blood flow to a muscle group may adversely alter the rate and/or extent of a drug-administered i.m. Decreased perfusion or hemostatic decompensation, frequently observed in ill neonates and young infants, may reduce i.m. drug absorption. Drug absorption may be adversely affected in neonates who receive a skeletal muscle-paralyzing agent such as pancuronium (16) because of decreased muscle contraction. A small muscle mass in neonates and young infants may also reduce the ability of a drug to be adequately absorbed.

The injection technique used may alter i.m. absorption. This was noted when needles of different lengths were used. The use of a longer needle (38 vs. 31 mm, 1 1/2 vs. 1 1/4 in.) for i.m. administration in adult patients resulted in higher diazepam serum concentrations (18). This probably occurred because the drug administered with the shorter needle was actually administered s.c. rather than i.m.

Some drugs are absorbed more slowly after i.m. than oral administration; examples include diazepam, digoxin,

and phenytoin. This probably occurs because these drugs require a mixture of alcohol, propylene glycol, and water for solubility, and they are insoluble in the muscle after i.m. administration (18).

Complications associated with i.m. administration include nerve injury, muscle contracture, and abscess formation (19). Less common problems include intramuscular hemorrhage, cellulitis, skin pigmentation, tissue necrosis, muscle atrophy, gangrene, and cyst or scar formation. In addition, injury may occur from broken needles and inadvertent injection into a joint or vein (19).

Subcutaneous Absorption

The s.c. route is used for the administration of drugs such as insulin that require slow absorption. Injection technique and patient factors, such as fluid status and physical build, are important (18). Exercise, elevation or warming of the injection site, or inadvertently administering a drug i.m. rather than s.c. can increase absorption and be dangerous in some situations, such as hypoglycemia occurring in a diabetic patient from excessive insulin absorption (18). Adverse effects that can occur secondarily to s.c. administration include tissue ischemia, sterile and nonsterile abscesses, lipodystrophy, cysts, and granulomatous formation.

Intraosseous Drug Absorption

If an i.v. line cannot be placed, the intraosseous drug administration route can be used for pediatric patients during, for example, cardiopulmonary resuscitation (CPR) because drug delivery by this route is similar to that for i.v. administration (20). If drug or fluid deliver by this route is sluggish, a saline flush can be used to clear the needle. Intraosseous administration is used to deliver medications such as epinephrine, atropine, sodium bicarbonate, dopamine, diazepam, isoproterenol, phenytoin, phenobarbital, dexamethasone, and various antibiotics (20).

Percutaneous or Transdermal Absorption

The percutaneous (transdermal or topical) route for systemic drug delivery is used infrequently for pediatric patients. Medications are typically applied to the skin for their local effect. In the future, this route may be used more frequently for systemic effects as more transdermal systems are developed for drug delivery.

The percutaneous absorption or the transdermal delivery of a drug occurs in the following manner. Initially a topically applied drug is absorbed into the stratum corneum and diffuses through that layer of skin

into the epidermis and then into the dermis where drug molecules reach capillaries and enter the circulatory system. Diffusion through the stratum corneum is the rate-determining step unless skin perfusion is decreased. If the latter case, diffusion is controlled by the transfer of drug molecules into capillaries rather than by the diffusion process previously explained. Percutaneous or transdermal absorption (21, 22) is affected by

- Patient age.
- Application site.
- State of hydration of the stratum corneum.
- Thickness and intactness of the stratum corneum.
- Physical characteristics of the solute, and
- Physical characteristics of the vehicle or solvent.

Drug diffusion may be explained by Eq. 1:

$$J = \frac{K_m \times D_m \times C_s}{\ell} \quad (1)$$

where J is flux, K_m is the partition coefficient, D_m is the diffusion constant under specific conditions such as temperature and hydration, C_s is the concentration gradient, and ℓ is the length or thickness of stratum corneum (21).

Lipid-soluble drugs are better absorbed into the stratum corneum than are water-soluble drugs, but the latter do not easily traverse the stratum corneum. Thus, lipid-soluble drugs are more likely to be stored in the stratum corneum, whereas water-soluble drugs are more likely to diffuse across the stratum corneum to the epidermis and dermis (21).

Patient age

Drug absorption transdermally is not appreciably different in various age groups of patients except for neonates less than 32-week gestation at birth (23). Drug absorption is increased in premature neonates, because the stratum corneum is not completely formed at birth. An example of increased drug absorption occurred in two premature neonates who were repeatedly washed with 3% hexachlorophene and developed encephalopathy secondary to drug absorption (21). The absorption of the corticosteroid betamethasone valerate after topical application in children resulted in hypothalamus–pituitary–adrenal axis suppression. Children may have increased drug absorption from the percutaneous application of drugs not because of higher absorption rate but because of a greater topical application or a larger dose per kilogram. Examples of deaths in children from percutaneous drug absorption include those caused by salicylic acid and phenol absorption (21). Toxicity has also been noted with

the topical application of iodine and alcohol-containing products (23).

Application site

The ability of a drug to be absorbed transdermally depends on the thickness of the stratum corneum. For example, absorption occurs more readily through abdominal skin than through skin on the plantar surface of the foot. Topical absorption may be enhanced from a particular site by the application of an occlusive dressing.

Status of the stratum corneum

Percutaneous absorption of a drug is enhanced by the hydration of the stratum corneum. Such hydration affects the absorption of hydrophilic drugs more than lipophilic drugs. Drugs will penetrate damaged skin more than intact skin. Skin damaged because of dryness will allow for increased drug penetration through areas where the skin is cracked or broken.

Solute

The penetration of the solute (or drug) depends on its polarity and on the polarity of the delivery vehicle.

Vehicle or solvent

Drug-delivery vehicles typically used for topical application include lotions, ointments, creams, emulsions, and gels. Substances such as emulsifiers may be added to the drug and vehicle to improve the texture of an emulsion, a stabilizer to preserve drug stability, the vehicle, or both, a thickening agent to increase viscosity, or a humectant to draw moisture into the skin (21). It is particularly important to consider the vehicle and other additives when selecting a topical drug preparation for a neonate, especially when premature, because of the greater possibility of absorption of not only the drug but also other product ingredients. Toxic reactions have occurred in neonates from ingredients considered “inactive.”

Transdermal Drug-Delivery Systems

Drugs chosen for delivery via a transdermal drug-delivery system must adequately penetrate the skin in such a way that the system determines the delivery rate that should be fairly constant (21). In addition, the drug must not irritate or sensitize the skin. It is hoped that in the future more drugs will be developed for transdermal delivery. This could become an alternative route for drug delivery to children who have difficulty with oral administration.

Endotracheal Absorption

The endotracheal (ET) route has been used to administer medications during CPR when other routes, such as the i.v. route, are unavailable. It provides rapid access as well as rapid drug absorption and distribution (24). Some studies have shown that the time to reach peak absorption is similar to that for the i.v. route, but serum concentrations achieved were 10–33% of that achieved with i.v. administration, resulting in a weaker response. A depot effect has also been demonstrated for drugs such as epinephrine. Work needs to be done to determine the optimal dose by this route, drug-delivery vehicle, and the most effective delivery technique.

Rectal Absorption

The rectal route is used for local and systemic therapy for the following reasons (25):

- Nausea or vomiting.
- Rejection of oral medication because of its taste, texture, etc.
- Upper GI disease that might affect absorption.
- Medication absorption affected by food or gastric emptying.
- Medication is readily decomposed in gastric fluid but may be stable in rectal fluid, and
- First-pass effect of high-clearance drug may be partially avoided.

Absorption from the rectum depends on various physiological factors such as surface area, blood supply, pH, fluid volume, and possible metabolism by microorganisms in the rectum. The rectum is perfused by the inferior and middle rectal arteries, whereas the superior, the middle, and the inferior rectal veins drain the rectum (25). The latter two are directly connected to the systemic circulation; the superior rectal vein drains into the portal system. Drugs absorbed from the lower rectum are carried directly into the systemic circulation, whereas drugs absorbed from the upper rectum are subjected to hepatic first-pass effect (25). Therefore, a high-clearance drug should be more bioavailable after rectal than oral administration. The volume of fluid in the rectum, the pH of that fluid, and the presence of stool in the rectal vault may affect drug absorption. Because the fluid volume is usually low compared to that in other areas of the GI tract, a drug may not be completely soluble. In addition, a variety of organisms colonize the rectum, and it is debated whether these organisms are involved in drug metabolism (25). Absorption is also influenced by the dosage form used. For example, drugs are rapidly absorbed rectally from aqueous or alcoholic solutions, whereas absorption

from a suppository depends on its base, the presence of a surfactant, particle size of the active ingredient(s), and drug concentration (25). The following problems may be associated with the rectal route for drug administration (25):

- Decreased absorption secondary to defecation of the rectally administered pharmaceutical product.
- Less absorption rectally than orally because the absorbing surface area of the rectum is smaller.
- Dissolution problems for rectally administered medications because of lower fluid volume in the rectum than in the stomach, duodenum, etc..
- Microorganisms in rectum may cause degradation of some medications, and
- Patient or parent acceptance.

Distribution

A drug is distributed by moving from a patient's systemic circulation to various compartments, tissues, and cells. Distribution depends on patient factors, drug physiochemical properties, and the route of drug administration. Patient factors that influence drug distribution or the volume of drug distribution (V_d) include body composition, perfusion, protein- and tissue-binding characteristics, and permeability (7, 8). Many of these characteristics are age dependent. Drug physiochemical properties that may influence distribution include molecular weight, pK_a , and partition coefficient.

Differences in body composition

Age-related changes in body composition can alter the V_d of a drug. At birth, 85% of the weight of a premature infant may be water, compared to approximately 75% as total body water (TBW) in a full-term infant (13). Neonates have the highest percentage of extracellular water (65% of TBW in premature infants as compared to 35–44% in full-term neonates and 20% in adults). The intracellular water (ICW) is more stable throughout life (i.e., 25% in premature neonates, 33% in full-term neonates, and 40% in adults) (7). An infant's percentage of TBW approaches that of an adult male by 1 year of age (60% TBW); it reaches the same about the time of puberty or 12 years of age (8). Women have a lower percentage of TBW (50%) than men do because they have a higher concentration of body fat. Thus, neonates, because of their high TBW, have a higher V_d for water-soluble drugs such as aminoglycosides than older children or adults. For example, the V_d for an aminoglycoside such as gentamicin approximates that of extracellular cellular fluid volume, 0.5–1.2 L/kg for a neonate, but only 0.2–0.3 L/kg for an older child or an adult (8).

Adipose tissue increases from as little as 0.5% in a premature infant to approximately 16% of body weight for a full-term infant (26, 27). Boys experience a spurt in body fat between the ages of 5 and 10 years, and then a gradual decrease in fat content until about 17 years of age; girls usually have a rapid increase in adipose tissue at puberty (9). Thus, one would expect neonates and young infants to have a decreased V_d for lipid-soluble drugs. This has been noted for diazepam in neonates who have exhibited an apparent V_d of 1.4–1.8 L/kg compared to 2.2–2.6 L/kg in adults (28).

Protein binding

Neonates have lower concentrations of various plasma proteins (e.g., albumin concentrations about 80% of those in adults) for drug binding, but the albumin present may also have a lower affinity for binding drugs than noted for adults who are receiving the same medications. This lower affinity for binding drugs may result in a competition for various albumin-binding sites with substances such as bilirubin. Plasma protein binding noted in adults is usually achieved in children by the age of 1 year (13).

In neonates drugs such as various penicillins, phenobarbital, phenytoin, and theophylline have lower protein-binding affinity than in adults. This may increase the concentration of free or pharmacological active drug in neonates, and may also change the apparent volume of distribution. Thus, neonates may require different doses on a mg/kg basis compared to that for adults for these drugs to achieve appropriate therapeutic serum concentrations.

In addition to binding to plasma proteins in the neonate, some drugs such as sulfonamides may displace plasma bilirubin from binding sites. This may increase an infant's risk for developing kernicterus. The significance of drugs displacing bilirubin is controversial because bilirubin may have a greater affinity for albumin than drugs have (29).

Tissue binding

The binding of drugs to various body tissues appears to vary with age; for example, digoxin binding to erythrocytes is higher in neonates than in adults. This may be due to the increased number of binding sites on neonatal erythrocytes (30).

Drug penetration into the central nervous system

A drug is more likely to cross into the central nervous system (CNS) of a neonate rather than an older child or an adult. This most likely occurs because its CNS is less mature and the blood–brain barrier is less formed. This is an important consideration when antimicrobial therapy is

needed for the treatment of bacterial meningitis or anticonvulsant for seizures.

Metabolism

Although drug metabolism can occur in various body organs including the lungs, GI tract, liver, and kidneys as well as in the blood, the liver is the primary organ for metabolism. Most drugs are metabolized from lipid-soluble parent compounds to more polar, less lipophilic metabolites that are more readily eliminated renally (9).

Hepatic metabolism

Most drug metabolism occurs in the liver by phase I or phase II metabolic processes. Phase I reactions primarily biotransform an active drug to a more water-soluble compound that typically is inactive or has less activity than the parent compound. Oxidation, reduction, hydrolysis, and hydroxylation are examples of phase I reactions (6, 8, 16). Oxidation is primarily catalyzed by the cytochrome (CYP) P450 system that has a multitude of isozymes (at least 13 primary enzymes) with a multitude of isozymes of specific gene families (6). It appears that isozymes CYP450 1A2, 2D6, 2C19, and 3A3/4 are involved in drug metabolism in humans (6). Oxidizing enzyme systems appear to mature after birth so that by the age of 6 months, activity is similar to or even exceeds adult levels. More information about drugs affected by phase I reactions may be found in (6).

Phase II reactions (glucuronidation, sulfation, acetylation, and glutathione conjugation) usually involve the conjugation of active drugs with endogenous molecules to form metabolites that are more water soluble (16); glucuronidation is the most thoroughly studied reaction. It is postulated that maternal glucocorticoids inhibit the development of glucuronyltransferase, the enzyme involved in glucuronidation in utero. After birth this metabolic system matures rapidly and reaches adult levels by the age of 2 years (29).

Sulfate conjugation appears to be fully developed immediately prior to or at the time of birth. Infants and young children readily sulfate acetaminophen; in adults the major metabolic route is glucuronidation (31). Little is known about acetylation in neonates or infants. It is believed that neonates have an extremely low capacity for acetylation at birth, but this pathway matures at approximately 20 days of age (29).

Theophylline is an example of a drug that is readily metabolized in neonates by N-methylation to caffeine (process not relevant clinically in older infants, children, and adults). It is also a compound that has pharmacologic

activity versus apnea (like theophylline), but which may have toxicity when it is not readily metabolized by the liver, and its elimination is slowed by immature kidneys (6).

Neonates require close monitoring if their mothers received enzyme inducers such as phenytoin, phenobarbital, carbamazepine, or rifampin during pregnancy or if they need one of these drugs themselves (16). Examples of drugs that inhibit the metabolism of other medications include cimetidine, erythromycin, and ketoconazole (16).

Renal Elimination

The kidneys are the major route for drug elimination, especially for water-soluble compounds or the metabolites of lipid-soluble drugs. Renal drug elimination is dependent on renal blood flow, glomerular filtration, and tubular secretion and reabsorption. These functions appear to mature at different rates in the neonate and infant. Full-term infants achieve renal blood flow similar to that of adults by the age of 5–12 months; glomerular filtration approaches adult values by the age of 3–5 months (6). Premature neonates exhibit lower rates for glomerular filtration at birth than do full-term neonates, and more time is required of them postnatally to develop filtration ability (32). This is probably due to their lack of as many functional nephrons at birth. Tubular function is less mature in the neonate at birth than is glomerular filtration, and it matures at a slower rate. Tubular function begins to approach adult values by 7 months of age. Renal function is equal to that of adults by 1 year of age.

Aminoglycosides (e.g., gentamicin, tobramycin, amikacin) and digoxin are drugs whose eliminations are affected by renal maturation. The renal elimination of aminoglycosides in neonates and young infants parallels the maturation of glomerular function and correlates with creatinine clearance (33). The renal elimination of digoxin parallels kidney maturation. Dosage adjustment for this drug is necessary as renal function matures in neonates and young infants. In addition, older infants and children require higher mg/kg doses of digoxin than do adults to achieve the same serum concentrations. This may be due to decreased digoxin absorption or increased renal elimination (8).

THERAPEUTIC DRUG MONITORING

Therapeutic drug monitoring should encompass the entire drug-use process including drug selection, product selection, administration route, patient age, appropriate

dosing on a mg/kg or mg/m² basis, and monitoring serum concentrations when appropriate and observing the patient for optimal drug effect(s) and possible adverse drug events.

Important Differences in Pediatric Serum Drug Concentrations

For many drugs, especially for those with narrow therapeutic indexes, serum concentration ranges have been determined that correlate to minimum and maximum therapeutic effects as well as to the development of toxicity. Therapeutic serum concentration ranges for various drugs have been developed for adults, and these data have been applied to pediatric patients including neonates. Such data may be appropriate to monitor drug therapy in children, but possibly not in children of all ages or possibly not in children at all. For example, Painter et al. (34) noted that neonates need higher serum phenobarbital concentrations than do older children and adults to terminate seizures. Gilman et al. (35) observed that higher phenobarbital loading doses were needed to achieve serum concentrations in neonates that would reduce the occurrence of seizures. Thus, there may be a need for different serum concentration ranges for various drugs needed by different age groups of patients for a similar pharmacodynamic or therapeutic outcome.

Free serum concentrations, rather than total concentrations, of some drugs such as phenytoin may need to be monitored in some patients, including neonates, who have low serum albumin. Gilman has advocated the possibility of using individualized dosing and serum concentration range for pediatric patients because children, especially neonates, have rapidly maturing functions of various organs and changes in albumin for drug binding (36).

Serum concentration monitoring of various drugs administered to pediatric patients may appropriately give information about the drug but not its metabolites. This may be a problem when children metabolize specific drugs differently than adults with resulting differences in metabolite concentrations or the presence of different metabolites. This has been noted when premature infants have been administered theophylline for central apnea. A major metabolite of theophylline in neonates is caffeine, although only small concentrations of this metabolite are noted in older children and adults (37, 38). Caffeine is effective in treating apnea, and thus may add to the effectiveness of theophylline. This may help explain why lower theophylline serum concentrations may be needed for apnea rather than asthma. In addition, the presence of the 4-en metabolite of valproic acid noted in the serum of infants and young children, but not adults, receiving this

medication for seizures may be responsible for the hepatotoxicity of this drug in young pediatric patients (36, 39).

Serum Drug Concentrations

Because of the cost associated with therapeutic drug monitoring, serum drug concentrations must be drawn appropriately to provide useful information. Drugs typically followed pharmacokinetically are those with narrow therapeutic indexes for which there is an association between pharmacokinetic and pharmacodynamic data or toxicity. For many drugs, especially for those administered orally, the determination of trough concentrations (serum concentrations obtained prior to administration) may be most appropriate. This eliminates differences in absorption rates that could influence peak concentrations (e.g., orally administered phenobarbital, phenytoin, carbamazepine, or valproic acid). Trough concentrations may be important for drugs such as digoxin that take time to distribute to tissue receptors in such a way that serum concentrations reflect pharmacodynamic effects. Peak concentrations are best used for determining toxicity and therapeutic effects of drugs with short half-lives.

Table 2 gives therapeutic serum concentrations and pharmacokinetic information for some drugs administered to pediatric patients.

Technical Factors

Sample size and timing of blood drawing for serum concentration determination

Because of the small blood volume and the small size of veins, it is technically difficult to draw blood from neonates, infants, and young children for therapeutic drug monitoring, and it is therefore important to determine the best drawing schedule. For example, when are peak and trough data needed compared to trough data only? For anticonvulsants administered orally or i.v., trough concentrations are needed, whereas for aminoglycosides it may be important to obtain both peaks and troughs.

DOSING REGIMENS

Drugs for pediatric patients should be dosed on a mg/kg or a mg/m² basis using information available for the patient's age group. In addition, the patient's renal and hepatic functions must be considered. The route for administration must be determined based on the severity of the illness, the availability of the medication for a particular route of

administration, and whether the patient is able to take a medication orally.

The Bibliography succeeding the References at the end of this chapter contains a list of handbooks and other references that are useful sources of dosing information for neonatal and/or pediatric pediatrics. In addition, drug information centers in pediatric hospitals or university settings are another excellent resource for pediatric drug information.

EXCIPIENTS OR ADDITIVES IN MEDICATIONS

Pharmaceutical products may contain, in addition to the active or therapeutic agent(s), a variety of other ingredients that are termed inactive or inert that are categorized as excipients or additives (flavorings, sweeteners, preservatives, stabilizers, diluents, lubricants, etc.). The words inert or inactive are misnomers for some excipients because some have been shown to cause adverse effects. Neonates and young children are at risk for such adverse effects, because they may not be able to metabolize or eliminate an ingredient in a pharmaceutical product in the same manner as an adult. In addition, patients of various ages have experienced allergic reactions to excipients such as tartrazine dyes.

Benzyl alcohol is a preservative that may be present in multidose vials of bacteriostatic sodium chloride and bacteriostatic water for injection and pharmaceuticals available in multidose vials for parenteral use. An association between the presence of benzyl alcohol in solutions used for flushing intravascular catheters and to reconstitute medications and a gasping syndrome and deaths in neonates was first reported in the early 1980s (40, 41). The neonates also displayed clinical findings such as an elevated anion gap, metabolic acidosis, CNS depression, seizures, respiratory failure, renal and hepatic failures, cardiovascular collapse, and death. Those at highest risk were premature infants who weighed less than 1250 g at birth (40–42). In a study by Benda et al., premature neonates who survived benzyl alcohol administration were compared to neonates born after the use of benzyl alcohol-containing flush solutions was discontinued (43). They noted that survivors had a higher incidence of cerebral palsy (50%) compared to infants who did not receive benzyl alcohol flushes (2.4%) ($P < 0.001$). In addition, the incidence of cerebral palsy and developmental delay was 53.9 versus 11.9% in the two populations ($P < 0.001$). The cause is probably associated with benzyl alcohol use and the inability of neonates, especially those who are premature, to adequately metabolize benzyl

Table 2 Pediatric pharmacokinetic data of some medications^a

Drug	Therapeutic serum concentration (μg/ml)	Bioavailability (for oral drugs) (%)	Plasma protein binding (%)	V _d (L/kg)	t _{1/2} (h)
Carbamazepine	4–12	>70	40–90	1.5 (neonate) 0.8–1.9 (child)	8–25 (child) t _{1/2} varies with multiple dosing
Clonazepam	20–80 ng/mL	>85	47–80	3.2 (child)	20–40 (child)
Ethosuximide	40–100	~100	0	0.6–0.7 (child)	24–36 (child)
Gentamicin	trough ≤ 2 peak 4–10	Not available	<30	0.4–0.6 (neonate) 0.3–0.35 (child)	3–11.5 (<1 wk) 3–6 (1 wk–6 mo) 1.2 (child)
Phenobarbital	15–40	80–100	40–60	0.6–1.2 (neonate) 0.7–1 (child)	45–173 (neonate) 37–72 (child)
Phenytoin	10–20	85–95	>90	1–1.2 (premature neonate) 0.8–0.9 (full-term neonate) 0.7–0.8 (child)	6–140 (<8 days) ^b 5–80 (9–21 days) ^b 2–20 (21–36 days) ^b 5–18 (child) ^b

alcohol (44). The American Academy of Pediatrics (45), the Centers for Disease Control (46), and the FDA (47) recommend that the administration of products containing benzyl alcohol be avoided in infants. Preservative-free i.v. flush solutions are recommended (45–47).

Initially, it was believed that benzyl alcohol was only toxic in neonates who received doses greater than 99 mg/kg (42), but it has been suggested that lower doses may be toxic, resulting in kernicterus and intraventricular hemorrhages (48, 49). Therefore, pharmaceutical preparations and fluids containing benzyl alcohol should be avoided in premature neonates.

Benzoic acid and sodium benzoate are added in low concentrations to various pharmaceutical preparations as bacteriostatic and fungistatic agents. Hypersensitivity reactions to benzoates have occurred when administered to allergic patients, such as those with asthma, those who do not tolerate aspirin, and those with a history of urticaria (44). Hyperbilirubinemia and systemic effects attributed to benzyl alcohol may occur in premature neonates because benzyl alcohol is metabolized to benzoic acid (44).

Propylene glycol is found as a solvent in some i.v. multiple vitamin preparations and a variety of pharmaceutical preparations for parenteral administration including phenytoin, digoxin, and diazepam. MacDonald et al. (50) noted that neonates who received MVI-12 (propylene glycol dose of approximately 3 g/day) versus those who received MVI concentrate (propylene glycol dose of approximately 300 mg/day) had a significant increase in seizures. In addition, infants in the first group suffered from hyperbilirubinemia and renal failure. (Although MVI concentrate is no longer on the market in the United States, it was used in the early 1980s.)

Serum hyperosmolality has been reported in infants who received vitamin preparations (51), and in burn patients due to the topical absorption of propylene glycol-containing products (52, 53). In addition, burn patients have experienced metabolic acidosis with a high anion gap, decreased ionized calcium concentrations, acute renal failure, and death from topical propylene glycol absorption (44, 54). Problems associated with the oral ingestion of propylene glycol-containing products by children include CNS depression, seizures, and cardiac dysrhythmias (55). Hypotension, cardiac dysrhythmias, respiratory depression, and seizures have occurred after the rapid administration of phenytoin that may be associated with the propylene glycol (56).

The American Academy of Pediatrics Committee on Drugs recommends that medications intended for pediatric use be ethanol free (57). If, because of stability or solubility problems with the active ingredient(s), liquid medications need ethanol as an ingredient, but they should

not contain more than 5% v/v ethanol (57). The Academy also recommends that the ingestion of a single dose of an ethanol-containing product by a pediatric patient should not result in blood ethanol concentrations greater than 25 mg/100 mL, the volume of a packaged liquid medication should be of a minimal amount so that its entire ingestion would not result in a lethal dose and safety closures should be on all medicinals containing greater than 5% v/v ethanol. In addition, the Academy suggests that children under 6 years of age who need an ethanol-containing OTC preparation be under medical supervision and that doses of any ethanol-containing product be spaced at intervals to avoid ethanol accumulation (57).

The Academy of Pediatrics made their recommendations concerning ethanol exposure from medications based on potential acute and chronic ethanol-related problems. Acutely, the coadministration of ethanol may alter drug adsorption or metabolism, and may result in drug interactions (e.g., increased sedation when taken with sedatives). Disulfiram-like reactions have occurred after the ingestion of an alcohol-containing medication or when an ethanol-containing product is used in conjunction with medications such as metronidazole, sulfonamides, chloramphenicol, or cefamandole (57). The CNS effects (muscle incoordination, a longer reaction time, behavioral changes) are the most commonly reported acute adverse reactions associated with ethanol ingestion. Such reactions have occurred with blood ethanol concentrations in the range of 1–100 mg/100 mL (57). Lethal ethanol doses in children occur at approximately 3 gm/kg although deaths due to ethanol-induced hypoglycemia have occurred at lower doses or because of interactions with other medications (57, 58). Chronic ethanol exposure may induce hepatic enzymes, and may thus alter the clearance of drugs such as phenytoin, phenobarbital, and warfarin (59). Examples of other additives that have been problematic in pediatric patients include lactose (55), tartrazine dyes (44, 55) and sulfites (55).

It is therefore important for health care professionals, and especially those who are responsible for selecting and administering medications to premature neonates, to examine pharmaceutical preparations for the presence of inactive ingredients as well as for the active drug. The provision of medications should be based on choosing the safest preparations possible. Various brands of medications should be compared to ensure that products without hazardous excipients. In the hospital setting, pharmacy and therapeutics committees and the pharmacy department play important roles in this process because they compare pharmaceutical preparations for formulary selection. In the outpatient setting, physicians and pharmacists must responsibly select the most appropriate

brand of a particular medication. Kumar et al. (60) recommend that labeling for pharmaceutical products should include the names and the amounts of excipients as well as active ingredients to help health care professionals select appropriate drug products for neonates.

INTRAVENOUS ADMINISTRATION

Without being properly instructed about methods used for administering i.v. medications to pediatric patients, health care personnel may give a medication incorrectly, resulting in an inappropriate or unexpected therapeutic response. Therefore, it is important that health care personnel (nurses, physicians, pharmacists) understand how medications are administered by this route.

The i.v. route is most frequently chosen for medication delivery when a patient's clinical condition requires that a medication be administered by the most expeditious and complete method possible. In addition, some drugs are only available for i.v. administration. Although this route is the most reliable for drug delivery to the systemic circulation, problems can occur that reduce and/or delay medication delivery because of the product selected, dosage volume needed, or frequency of administration, but problems can also be associated with the i.v. delivery system used. The latter occur most frequently when a small medication volume is administered at a slow rate as is often needed for a neonate or young infant. A brief discussion of problems associated with i.v. drug delivery to pediatric patients is given here. A thorough overview of i.v. drug administration to pediatric patients is provided in Refs. (61 and 62).

Disposable IV Equipment, Effects on Drug Delivery

Infusion rates and location of injection sites

The first article to explore problems that can occur with i.v. drug delivery to pediatric patients was published in 1979 by Gould and Roberts (63). They demonstrated in their study using an in vitro system for drug administration (Fig. 1) that infusion rates as well as the location of the injection sites in the i.v. infusion system influence the infusion profile of i.v. administered medications. Figure 1 shows the effects of different i.v. fluid rates on the length of time to infuse 95% of a gentamicin dose administered at various sites in the infusion system (63). It was reported that at a slow infusion rate of 3 ml/h, a drug takes longer to be infused and that the time for infusion time depends on the site of administration (i.e., the further the drug

Fig. 1 Intravenous administration system used by Gould and Roberts. (From Ref. 63.)

injection from a patient, the longer to administer 95% of the medication, see Figs. 2,3). Thus, it took approximately 400 min to infuse gentamicin at an infusion rate of 3 ml/h via a Y-site in the administration system. However, the same drug administered at a butterfly injection site at the same fluid flow rate reduced the length of time to administer 95% of the drug to less than 20 min. Gould and Roberts also stated that the time needed for drug administration in their i.v. system was longer than what had been expected (63).

Type of injection site

Leff and Roberts (61) demonstrated that the amount of drug received by a pediatric patient and the drug-delivery rate are influenced by the type of injection site (Y-site, T-type, T-connector, stopcock, etc.) and the volume (dead space) contained in the particular site. For the delivery of small dosage volumes (less than 1 ml) i.v. tubing should have microinjection sites that prevent a drug from being sequestered in the injection site. In addition, the amount of i.v. fluid needed to adequately flush microinjection sites to clear the medication would be less than needed to flush injection sites found on tubing used to administer drugs to adults.

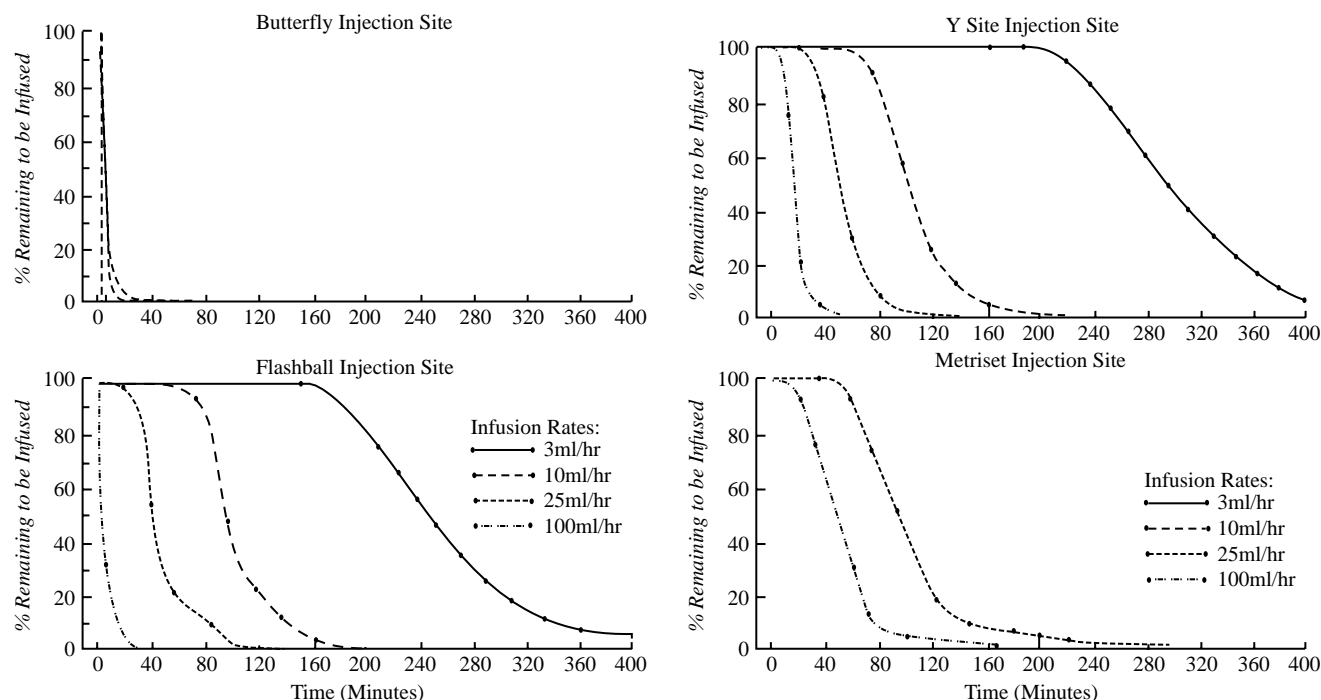

Fig. 2 Influence of i.v. flow rate on the infusion profile of gentamicin. (From Ref. 61.)

Fluid flow dynamics

Another characteristic of i.v. tubing that affects drug delivery is fluid flow dynamics. It appears that flow in i.v. tubing is best characterized by laminar flow, and the radius of the tubing. Poiseuille's law describes flow in i.v. tubing as

$$\frac{q_v}{4nL} = \frac{Pr^4}{4nL} \quad (2)$$

where q_v is the volumetric flow rate, P is the pressure change in the i.v. tubing, r is the radius of the i.v. tubing, n is the viscosity of the fluid, and L is the length of the i.v. tubing.

Thus, for i.v. delivery to pediatric patients, microbore tubing with an intraluminal diameter of <0.06 in. should be used rather than macrobore tubing. The use of microbore tubing allows the use of longer tubing lengths without significantly increasing delivery time.

Filters

A filter, especially one with a large reservoir volume, may prolong and/or reduce drug delivery. This occurs if the drug and its diluent are of different densities and there is a layering out of the drug in the filter (64). Therefore, a filter with a smaller reservoir volume should be selected.

Drug and Fluid Considerations for Intravenous Drug Administration

Characteristics of the drug and the fluid such as drug volume, osmolality, pH, and density may affect i.v. drug delivery. The frequency and duration of drug administration is also important as is the need for the infusion system to handle multiple drugs. This may lead to drug incompatibilities and problems in medication scheduling.

Osmolality and pH

Osmolality and pH must be considered when preparing a drug solution for i.v. administration to pediatric patients. Problems such as tissue irritation, pain on injection, phlebitis, electrolyte shifts, and even intraventricular hemorrhages in neonates have been associated with the administration of drug solutions with high osmolalities (65). Drug solutions should have osmolalities similar to serum osmolality, if possible. To control the osmolality, a drug can be diluted with a vehicle selected for i.v. infusion via a syringe infusion system (65) or the i.v. flow rate can be adjusted to achieve a particular drug-vehicle osmolality (61).

Density

If the density of a drug is significantly different from that of the diluent, the drug may layer out on the filter or in the i.v. tubing. The latter occurs more frequently if macrobore

tubing, a low flow rate, the i.v. system, or if the tubing is in a particular position. A density problem can be avoided by using microbore tubing which promotes mixing; this is especially important when i.v. flow rates are low, as are needed for neonates or young infants.

Frequency and Duration of Drug Administration; Multiple Drugs

To ensure that frequent doses are administered at appropriate intervals or that multiple drugs are administered to avoid drug incompatibilities, a syringe infusion pump can be used to administer drug volumes over a specific length of time. This helps avoid a situation where part of a drug dose is left in the tubing when the i.v. set is changed, as has been reported for manual administration techniques. More than one syringe pump can be used to simultaneously administer compatible drugs in a parallel system into a micro-Y-site or stopcock.

Types of Intravenous Administration

Drugs may require i.v. administration as continuous infusions or at intervals (q4h, q6h, q12h, etc.). Manual methods require the administration of the drug into the i.v. system at an injection site (Y-site, T-connector, stopcock, etc.), added to the i.v. solution in a mixing chamber, or added to an i.v. bag to be administered via gravity. A syringe pump or another mechanical device may be used for drug administration.

Manual administration

Manual administration is not as accurate as using a syringe pump for drug administration. It has been used for small volumes of medication (< 3 ml), a low flow rate (< 20 ml/h), or if the antegrade (forward toward the patient) injection of a drug bolus is safe (61). If a medication is to be administered antegrade, it should be administered slowly into a microinjection site toward the patient; microbore tubing should be placed between the injection site and the patient to reduce the time to get the drug to the patient. Leff and Roberts (61) recommended that the volume of the drug to be injected by the antegrade technique should be a smaller volume than the tubing fluid volume between the injection site and the patient. If the medication volume is too large to be safely given by antegrade administration, but the i.v. fluid flow rate is low (< 20 ml/h), the drug may be administered by a retrograde technique (Fig. 3).

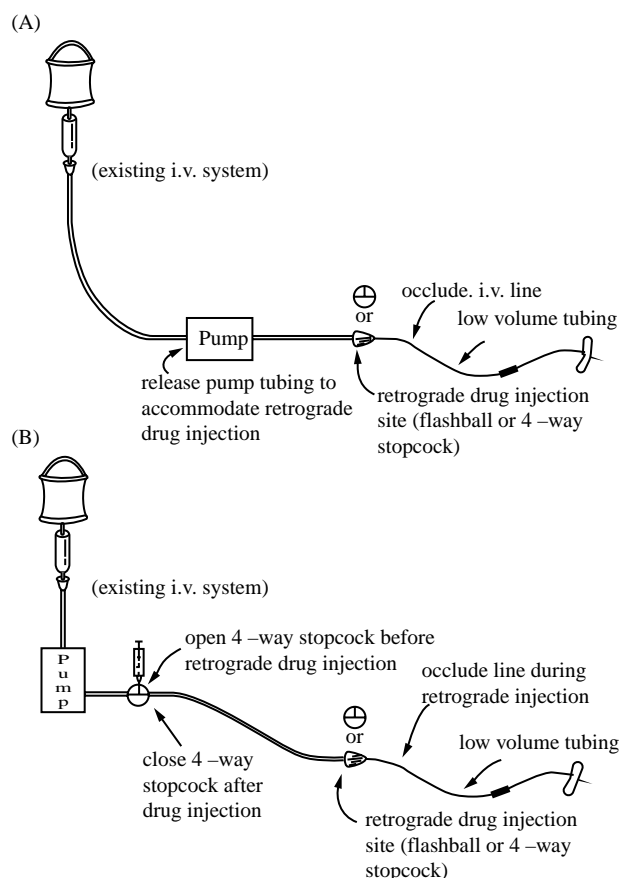

Fig. 3 Examples of retrograde system setups. (From Leff, R.D.; Roberts, R.J. Methods for intravenous drug administration in the pediatric patient. *J. Pediatr.* 1981, 98, 631–635.)

Mechanical system for drug administration

If a mechanical system is chosen for drug administration, the appropriate infusion device must be selected based on its operating mechanism, flow accuracy, flow continuity, and ability to detect occlusions. Other important factors include an alarm system, ease of operation, ability to be cleaned easily, and safety from children inadvertently trying to change pump settings. A syringe pump is best for delivering small dosage volumes and when intermittent intervals are needed for medications. It is the mechanical device most often selected for medication administration because it can be used for intermittent administration of small and large doses, or for the continuous infusion of medications at low rates. A drug can be administered separately from the primary i.v. fluid flow rate, with the drug and the fluid mixing for a short distance therefore in microbore tubing (see Fig. 4) before reaching the patient. In addition to being able to more accurately deliver medications than by manual methods,

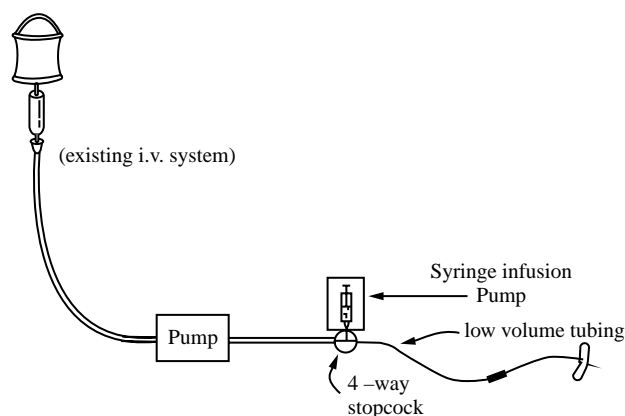

Fig. 4 Syringe pump setup with drug administered separately of the primary i.v. fluid flow rate. Mixing of the drug and i.v. fluid occurs at a stopcock and for a short distance in microbore tubing. (From Leff, R.D.; Roberts, R.J. *Methods for intravenous drug administration in the pediatric patient.* J. Pediatr. 1981, 98, 631–635.)

syringe pump systems have the advantage of being able to separate the administration of incompatible drugs, reduce difficulties associated with the administration of multiple doses, and shorten the time required to administer medications.

Additional Comments about IV Drug Administration

Reed and Gal (6) recommended the following steps to decrease problems associated with i.v. drug administration to pediatric patients:

1. Standardize and document total time for drug administration.
2. Document the volume of any solution used to flush an i.v. dose.
3. Standardize infusion techniques for drugs administration, especially for those with a narrow therapeutic index.
4. Use the largest gauge cannula that can be used.
5. Standardize dilution and infusion volumes for drugs given by intermittent i.v. injection, and avoid attaching lines for drug infusion to a central hub with solutions infused at widely disparate rates, and
6. Use low-volume i.v. tubing and use the most distal sites for drug administration.

In addition, one must remember that for infants the amount of fluid required for drug administration may take away from the amount of fluid available for nutrition. Thus, with medication administration, the fluid volume

must be as restrictive as possible so that the bulk of the daily fluid intake can be saved for nutrition. Health care providers must closely monitor daily fluid intake from all sources to prevent fluid overload and must also watch the osmolality of medications with diluents.

ADMINISTRATION OF ORAL MEDICATIONS

The oral route is typically the preferred route for medication administration to pediatric patients. Other routes may be used, if the patient cannot take a medication orally because of vomiting, being unable to swallow, or the medication is unavailable for oral use. In addition, for specific problems it may be better to deliver the medication directly to the area being treated, for example, inhalation, ophthalmic administration, or otic administration.

Dosage Forms

Oral liquids

Liquid medications are the most commonly administered oral medications to pediatric patients because of the ease of swallowing by infants and young children who cannot swallow solid dosage forms. However, availability of some medications as liquid formulations may be limited. If not available in liquid form, a solid dosage form may need to be modified by the pharmacist, other health care provider, or by the parent. If a solid dosage form is modified, for example a suspension is prepared, will the drug be stable and for how long, and will it be absorbed differently than the original dosage form? These are just a few questions that must be answered about the extemporaneous preparation of a drug product for a pediatric patient.

Alcohol-free products should be selected for pediatric patients whenever possible. Furthermore, the inactive ingredients or excipients contained in an oral preparation should be identified. this is especially important if the patient is known to have had an adverse reaction to a particular excipient or there is another reason to avoid a particular additive in a medication. The Committee on Drugs of the American Academy of Pediatrics recommended that pharmaceutical products contain a qualitative listing of inactive ingredients in order that products containing these substance could be avoided in patients who had problems with specific adjuvants (55). Kumar et al. (60) contains lists of inactive ingredients (sweeteners, flavorings, dyes, and preservatives) found in

Table 3 Osmolalities of liquid pharmaceuticals for oral administration

Liquid preparation	Osmolality (Mean \pm SEM)
Propylene glycol	8326 \pm 1467
Saccharin-containing drugs	
Albuterol	65
Haloperidol	47
Suspensions	2500 \pm 246
Sugar-containing ^a drugs	5574 \pm 594

^aSucrose, mannitol, glucose, and others.
(From Ref. 66.)

many liquid medications such as analgesics, antipyretics, antihistamine decongestants, cough and cold remedies, antidiarrheal agents, and theophylline preparations. The authors of the previous article and Golightly et al. have reviewed adverse effects associated with many inactive ingredients (44, 60).

Liquid medications, taken orally, can cause diarrhea and other GI symptoms, or they may aggravate GI distress that a patient is already experiencing. These GI effects can be associated with the high osmolality of some oral liquids. Osmolalities have been determined for various oral liquids (66). For preparations containing propylene glycol, or various sugars (e.g., sucrose, mannitol, glucose), osmolalities were noted to be high (see Table 3). It is important to compare various brands of liquid medications because they may contain different excipients and may have different osmolalities.

Sustained-Release Preparations

Most medications have shorter half-lives in children than in adults, and therefore children may need sustained-release products to maintain serum concentrations in the therapeutic range. For example, a sustained-release theophylline product may be needed for a child with asthma. It may need to be administered every 8 h to the child as compared to every 12 h for a healthy, nonsmoking adult to maintain therapeutic serum concentrations. When choosing a sustained-release theophylline preparation for a child, it must be remembered that because of differences in release properties, theophylline sustained-release products are not interchangeable. A product selected for the pediatric asthma patient should be reliably absorbed with a minimal serum concentration variation and not a preparation that has exhibited a difference in bioavailability when administered with or without food (67–69).

Extemporaneous liquid preparations

Because many medications are not available as liquid preparations, there are times when powder papers or suspensions must be prepared. An excellent information source about the preparation of liquid dosage forms for pediatric patients has been published by Nahata and Hipple (Nahata, M. C., Hipple, T. F. *Pediatric Drug Formulations*, 4th Ed. Harvey Whitney Books: Cincinnati, 2000).

Product selection

Products for oral administration should be in a dosage form most readily taken by the child. If the child is old enough to participate in the decision-making process, he or she may state a preference for a liquid, chewable tablet, tablet, or capsule, if the needed drug is available in a variety of dosage forms and appropriate dosage. If a liquid medication is needed, a product should be chosen based on texture, taste, and ease of administration. Other factors that must be considered are the absence of alcohol and dyes, and an osmolality that is close to physiologic (280–290 mOsm/kg). Are there excipients or adjuvants in the product, and if so, what are they and what is their concentration? Is there bioavailability information or pharmacokinetic information for the oral medication in pediatric patients, and if so, in what age groups? Is there information about the extemporaneous product that is to be prepared?

Rebecca Chater, a North Carolina pharmacist, recommends that pediatric patients be involved in medication counseling in order to improve their understanding of why a medication is needed. In the counseling process, the word medication should be used and not drug because of the connotation associated with the latter in today's society (70, 71). Wheeler recommends that, when possible, a product be selected that requires the fewest number of doses administered per day, for example, every 12 h dosing rather than every 8 h, so the medication does not need to be taken to school or day care for administration. If a medication must be given outside of the home, she recommends that two small labeled bottles be dispensed or one large bottle with a small empty bottle labeled to be used for medication administration at day care or school.

Health care providers including nurses, pharmacists, and physicians should demonstrate to parents and older children how medications should be administered and offer appropriate dosing devices (oral syringe, dropper, cylindrical medication spoon, or a small-volume doser with attachable nipple) to enable parents to accurately measure liquid products. A household teaspoon or tablespoon should not be used for medication administration because they are inaccurate. Kraus and Stohlmeyer

(72) explain the use of a new oral liquid medication delivery system that can be used for infants and young children who still use a bottle for feeding.

Administration techniques

The following information is presented to help health care providers counsel parents and older children on how medication should be administered by various routes.

Oral liquids

An oral liquid medication needed for an infant or young child should be shaken well, if required, accurately using an appropriate device. If a dropper or an oral syringe is used, the liquid should be administered toward the inner cheek. Administration in the front of the mouth may allow the child to spit out the medication, whereas administration toward the back of the mouth may result in gagging or choking. The oral syringe should be of an appropriate size to allow for administration into the inner cheek.

Oral solid dosage forms

A medication available only as a solid dosage form, may be prepared as an extemporaneous liquid (e.g., suspension) or it may be modified for oral use, for example, by crushing. As mentioned previously, a sustained-release product should not be crushed or chewed. For a solid, nonsustained-release medication, the product can be crushed and mixed with a small amount of food just prior to administration. Examples of foods that may be used for mixing include applesauce, yogurt, or instant pudding, but the medication should not be added to an entire dish of food or to infant formula, because the infant or child may not eat/drink the entire portion and thus not receive the total amount of medication.

OTHER ROUTES

Intramuscular Administration

Absorption of i.m. administered medications depends on the injection site because perfusion of individual muscle groups differs. For example, drug absorption from the deltoid muscle is faster than that from the vastus lateralis that is more rapid than from the gluteus (16, 17). In addition, lower perfusion or hemostatic decompensation, frequently observed in ill neonates and young infants, may reduce i.m. absorption. It may also be decreased in neonates who receive a skeletal muscle-paralyzing agent such as pancuronium because of decreased muscle contraction.

In addition, the smaller muscle mass of neonates and young infants provides a small absorptive area.

The injection technique and the length of the needle used may affect drug absorption, and thus serum concentrations. For example, using a longer needle (1½ vs. 1¼ in. or 3.8 vs. 3.1 cm.) for i.m. administration resulted in higher diazepam serum concentrations in adults (18). Therefore, it is important to select the appropriate site for drug administration as well as the appropriate length and needle bore. Sites that can be used for i.m. administration include anterior thigh and vastus lateralis, gluteal area and deltoid.

The midanterior thigh (rectus femoris) and the middle third of the vastus lateralis are used for i.m. administration to young infants as well as to older children (19). These sites are better developed and larger than other muscle groups that are used for drug administration to older children or adults. The technique is shown in Fig. 5 (19). With the patient lying supine, the “needle should be inserted in the upper lateral quadrant of the thigh, directed inferiorly at an angle of 45° with the long axis of the leg and posteriorly at a 45° angle” (19) to the surface on which the patient is lying. The person administering the injection should compress the tissues of the injection site to help stabilize the extremity. A 1-in. (2.5-cm) needle has been recommended for pediatric patients by Bergeson et al. (19) while Newton et al. (18) recommend a 23–26 gauge 1½-in. (3.8-cm) needle. The volume of drug that can be administered in this manner is 0.1–1 ml in infants and 0.1–5 ml in older children and adults (18).

The gluteal musculature develops as the infant or child increases his or her mobility; it becomes a more suitable injection site in children who are walking (18, 19). Damage to the sciatic nerve is the major problem associated with this injection site, and it occurs more commonly in infants because of their lack of gluteal muscle mass (73). Injury to the gluteal nerve, resulting in muscle atrophy, has occurred even when the injection technique was appropriately performed (19). Other nerves including the pudendal, posterior femoral cutaneous, and the inferior cluneal nerves have been damaged because of poor injection technique (19). Additional adverse effects associated with this drug administration route are discussed by Bergeson et al. (19).

A technique for gluteal administration is shown in Fig. 6 although other techniques are also used (19). All techniques involve the determination of the upper outer quadrant (see Fig. 6 for anatomical landmarks). After the location of the upper outer quadrant is determined, the needle should be inserted at a 90° angle to the surface on which the patient is lying, not to the patient’s skin (19). This site can be used for older children. A 1-in. (2.5-cm)

Fig. 5 A technique for anterior lateral-thigh intramuscular injection. (From Ref. 19.)

needle has been recommended (19). The volume of drug that can be administered in this manner is 0.1–5 ml for older children and adults (18).

The ventrogluteal (gluteus medius and minimus) site may be less hazardous for i.m. administration than the dorsogluteal (gluteus maximus) site (19). The technique is shown in Fig. 7 (19). The person administering a drug i.m. ventrogluteally should first note the anatomical landmarks (anterior superior iliac spine, tubercle of the iliac crest, and upper border of the greater trochanter). The needle is inserted into a triangular area bounded by these landmarks while the patient is in the supine position. The location for this injection can be determined “by placing the palm over the greater trochanter, the index finger over the anterior superior iliac spine, and spreading the index and middle fingers as far as possible” (19).

The deltoid muscle can be used for i.m. injections in older children, but it is not an option for young infants and children because of their limited muscle mass. Although

there are few complications associated with this administration route, nerve injury can occur (21). The technique is shown in Fig. 8 (19). The area for deltoid administration should be fully visible so that the anatomical landmarks can be visualized. Then the needle for deltoid injection should enter the muscle halfway between the acromion process and the deltoid tuberosity to avoid hitting the underlying nerves (19). The drug volume that can be administered by this route to older children and adults is 0.1–2 ml (18). The recommended needle length for older children is 1 in. (2.5 cm).

Subcutaneous Administration

The s.c. route is used for drug administration, such as insulin, that requires slow absorption. It is not commonly employed for medication administration for pediatric patients but is used for specific drugs. Typically a 1/2- or 1-in. (1.25- or 2.5-cm) needle is used with the volume of

Fig. 6 A technique for gluteal-area intramuscular injection. (From Ref. 19.)

drug that can be administered by this route ranging from 0.1 to 1 ml (drug volume administered depends on patient size).

Percutaneous Administration

The skin should be thoroughly cleaned prior to applying a topical ointment, cream, etc. A thin layer of ointment or

Fig. 7 von Hochstetter technique for ventrogluteal intramuscular injection. (From Ref. 19.)

Fig. 8 A technique for deltoid intramuscular injection. (From Ref. 19.)

cream should be applied to the prescribed area to reduce the possibility of a toxic reaction. The area of the skin where the medication is applied should not be covered or occluded unless instructed to do so by the physician because this procedure may increase drug absorption. Specific information should be given on how to cover the area.

Rectal Administration

Before the administration of a rectal suppository, the child's rectal area should be thoroughly cleaned. The infant or child should be placed on his or her side or stomach. The wrapper should be removed from the suppository and its pointed end should be inserted into the rectum above the anal sphincter. (If only half a suppository is prescribed, the suppository should be cut lengthwise before administration.) A finger cot or finger wrapped in plastic can be used for administering the suppository (74). Because an infant or small child cannot adequately retain a suppository in the rectum, the buttocks can be held together firmly for a few minutes after rectal administration to hold the suppository in place (74).

Otic Administration

Otic preparations should be at room temperature prior to administration. If the otic product is a suspension, it should be gently shaken for approximately 10 sec. before

administration (74). The child should be lying on his or her side, and the earlobe should be gently pulled down and back to straighten the outer ear canal (for adults the earlobe is pulled up and back). Then the prescribed number of drops should be instilled into the ear without placing the dropper in the ear canal. The patient should be kept in a position with the ear tilted for approximately 2 min to help keep the drops in the ear (75). This procedure may be repeated for the treatment of the other ear, if needed. The tip of the dropper should be wiped with a clean tissue after use.

Nasal Administration

For adults, the first step in administering nose drops or a nasal spray is blowing the nose to clear the nasal passages of mucus and other secretions, but infants and young children are unable to do this. Therefore, the nasal passages may need be cleared with a bulb syringe prior to medication administration. A child should lie down on his or her back, or a young infant or child should be placed in a lying position, and the head should be tilted slightly backwards. An appropriate amount of medication should then be placed in each nostril. Thereafter, the infant or child should remain quiet for a few minutes to allow the medication to be absorbed. The dropper should be rinsed with hot water before it is returned to the medication container.

Ophthalmic Administration

An ophthalmic medication should be at room temperature prior to administration. If the eye drops are in a suspension, the container should be gently shaken before administration. A child old enough to follow directions should tilt his or her head slightly backward and to the side so that the eye drops will not drain into the tear ducts near the nose. The eyelids should be separated and the patient should be asked to look up. The appropriate amount of medication is instilled into the lower eyelid, using the medication dropper, which should be accomplished without touching the eyelids. The patient should look downward for a few seconds after drug administration. The eye(s) should then be closed for several minutes in order to spread the medication across the eyeball and be absorbed if the effect is to be systemic (76). In addition, it has been recommended to gently put pressure on the inside corner of the eye for at least a minute to retard drainage of the medication (74). If a squeeze bottle is used, the appropriate amount of medication should be gently squeezed into the eye(s). For each of these methods, the dropper or the tip of the squeeze bottle should be kept away from the eye or skin to avoid contamination of the administration device (76). The

dropper should not be rinsed after use because this could lead to contamination of the dropper and the medication. The package insert should be reviewed for specific information.

Another method for administering eyedrops to children recommends that the drops be applied to the inner canthus of the eye while the patient keeps his/her eyes closed until told to open them after medication administration (77). Approximately 66% of the medication administered in this fashion was absorbed. In addition, this method may increase compliance and make children more cooperative.

For the administration of an ophthalmic ointment to a child who can cooperate, the child should tilt his or her head backwards and look up. After the hands have been washed, the person to administer the medication should gently pull down the lower eyelid(s) for drug administration. A thin layer of ointment should then be placed in the lower eyelid(s). Afterwards, the eyelid(s) should be closed for 1 to 2 min to allow for the spreading of the medication and absorption. During this process, the tip of the ophthalmic applicator should not touch the eye. After administration is completed, the tip of the applicator tube should be cleaned with a clean tissue and be tightly capped (76). The package insert should also be reviewed for specific information.

Inhalers

For the use of an inhaled medication (e.g., β_2 -agonists, corticosteroids, antivirals, cromolyn, etc.), it is crucial for the child and parents to understand the mechanism of the metered dose inhaler (MDI) or nebulizer, if used. The package insert should also be reviewed for information about the specific drug product. A decision may also need to be made as to whether a spacer may be needed for use with the medication canister.

PELLETIZATION TECHNIQUES

Isaac Ghebre-Sellassie

Pfizer Global Research and Development, Morris Plains, New Jersey, U.S.A.

Axel Knoch

Pfizer Global Research and Development, Freiburg, Germany

INTRODUCTION

Historically, the term *pellet* has been used by a number of industries to describe a variety of agglomerates produced from diverse raw materials, using different pieces of manufacturing equipment. These agglomerates include fertilizers, animal feeds, iron ores, and pharmaceutical dosage units and thus do not only differ in composition but also encompass different sizes and shapes. As a result, pellets meant different things for different industries. In the pharmaceutical industry, pellets can be defined as small, free-flowing, spherical particulates manufactured by the agglomeration of fine powders or granules of drug substances and excipients using appropriate processing equipment. The term also has been used to describe small rods with aspect ratios of close to unity. Although pellets have been used in the pharmaceutical industry for more than 4 decades, it has only been since the late 1970s, with the advent of controlled-release technology, that the advantages of pellets over single-unit dosage forms have been realized.

Pellets offer a high degree of flexibility in the design and development of oral dosage forms. They can be divided into desired dose strengths without formulation or process changes and also can be blended to deliver incompatible bioactive agents simultaneously and/or to provide different release profiles at the same or different sites in the gastrointestinal (GI) tract. In addition, pellets, taken orally, disperse freely in the GI tract, maximize drug absorption, minimize local irritation of the mucosa by certain irritant drugs, and reduce inter- and inpatient variability (1).

Given the enormous advantages of multiparticulate systems over single-unit oral dosage forms, extensive research has focused recently on refining and optimizing existing pelletization techniques as well as on the development of novel manufacturing approaches that use innovative formulations and processing equipment. The most commonly used and intensely investigated

pelletization processes are powder layering, solution/suspension layering, and extrusion-spheronization and are defined first and then addressed in detail.

Powder layering involves the deposition of successive layers of dry powder of drug or excipients or both on preformed nuclei or cores with the help of a binding liquid. Because powder layering involves the simultaneous application of the binding liquid and dry powder, it generally requires specialized equipment. The primary equipment-related requirement in a powder-layering process is that the product container should have solid walls with no perforations to avoid powder loss beneath the product chamber before the powder is picked up by the wet mass of pellets that is being layered on.

Solution/suspension layering involves the deposition of successive layers of solutions and/or suspensions of drug substances and binders on starter seeds, which may be inert materials or crystals/granules of the same drug. In principle, the factors that control coating processes apply to solution or suspension layering and, as a result, require basically the same processing equipment. Consequently, conventional coating pans, fluid-bed centrifugal granulators, and Wurster coaters have been used successfully to manufacture pellets. The efficiency of the process and the quality of pellets produced are in part related to the type of equipment used.

Extrusion-spheronization is a multistep process involving dry mixing, wet granulation, extrusion, spheronization, drying, and screening. The first step is dry mixing of the drug and excipients in suitable mixers followed by wet granulation, in which the powder is converted into a plastic mass that can be easily extruded. The extruded strands are transferred into a spheronizer, where they are instantaneously broken into short cylindrical rods on contact with the rotating friction plate and are pushed outward and up the stationary wall of the processing chamber by centrifugal force. Finally, owing to gravity, the particles fall back to the friction plate, and the cycle is repeated until the desired sphericity is achieved.

Other pelletization processes that either have limited application or are still at the development stage include

Fig. 1 Schematic representation of centrifugal fluid-bed equipment and process with a single-walled product chamber. (A) Glatt GPCG and GRG Granulators. (B) Freund CF-Granulators. (Adapted from Ref. 5).

spherical agglomeration or balling, spray congealing/drying, and emerging technologies such as cryopelletization and melt spheronization. These processes are addressed briefly.

POWDER LAYERING

The first equipment used to manufacture pellets on a commercial scale was the conventional coating pan, a machine that has been used by pharmaceutical firms, primarily for sugar coating, for a long time. During the 1950s, the industry, in an attempt to prolong the release of drugs from solid oral dosage forms, explored new processes that allowed the manufacture of multiparticulate drug-delivery systems. The turning point came when candy seeds, which had been used for topping decorations

in foodstuffs such as pastries, were used as starter seeds to develop and manufacture sustained-release pellets using conventional coating pans (2). The process was an extension of a procedure that was used to manufacture the candy seeds themselves and involved the successive layering of powder and binder solution on sugar crystals (3). Consequently, the conventional coating pan became the first pharmaceutical equipment used not only to manufacture nonpareils but also to develop sustained-release products of a number of prescription drugs using nonpareils as starter seeds.

Conventional coating pans, however, have had significant limitations as pelletization equipment. The degree of mixing is very poor, and the drying process is not efficient. Mixing is a function of the pan shape, the tilt angle, the baffle arrangement, and the rotational speed of the pan itself. These parameters must be optimized to provide uniform drying and sufficient particle movement to eliminate the potential formation of dead spots during the operation and to maximize yield. For instance, during pelletization, elliptical pans tend to have fewer stagnant spots than do cylindrical pans and, consequently, are the equipment of choice (4). Reducing the tilt angle can also minimize formation of dead spots. If the rotational speed of the pan is too slow, segregation may occur owing to percolation and induce the preferential layering of drug onto larger particles. In addition, prolonged contact time among the particles could favor particle agglomeration if the liquid feed rate leads to surface wetness and stickiness that induce coalescence.

During powder layering, a binding solution and a finely milled powder are added simultaneously to a bed of starter seeds at a controlled rate. In the initial stages, the drug particles are bound to the starter seeds and subsequently to the forming pellets with the help of liquid bridges originated from the sprayed liquid. These liquid bridges are eventually replaced by solid bridges derived either from a binder in the application medium or from any material, including the drug substance, that is soluble in the liquid. Successive layering of the drug and binder solution continues until the desired pellet size is reached. Throughout the process, it is extremely important to deliver the powder accurately at a predetermined rate and in a manner that maintains equilibrium between the binder liquid application rate and the powder delivery rate. If the powder delivery rate is not maintained at predetermined equilibrium levels, overwetting or dust generation may occur, and neither the quality nor the yield of the product can be maximized. Toward the end of the layering process, it is likely that fines may be generated owing to potential interparticle and wall-to-particle friction and appear in the final product, thereby lowering the yield. The problem can

be overcome if the application medium is sprayed on the cascading pellets at the end of the layering process to increase the moisture level at the pellet surface and facilitate layering of the fines onto the pellets. Caution must be exercised, however, not to overwet the product bed because the powder-liquid equilibrium that has been established will change and will need to be adjusted accordingly. In an ideal process, no agglomeration occurs, and the particle population at the end of the process remains the same as that of the starter seeds or cores, with the only difference being an increase in the size of the pellets and thus in the total mass in the pan.

Pieces of equipment that overcame the limitations of coating pans and revolutionized powder-layering processing as a pelletization technique are tangential spray or centrifugal fluid-bed granulators. Although tangential spray equipment was originally developed to perform granulation processes, its application was later expanded

to cover other unit operations including the manufacture and coating of pellets.

Although there are variations in the design of centrifugal or rotary granulators, the basic operational principle that determines the degree of mixing and thus the efficiency of the process remains the same and includes centrifugal force, fluidization air velocity, and gravitational force (Fig. 1). During a layering process, these three forces act in concert to generate a spiral, rope-like motion of the particles in the product bed. The rotating disk, which may have fixed or variable speeds, creates a centrifugal force that pushes the particles outward to the vertical wall of the product chamber or stator. The fluidization air, which is directed toward the slit between the periphery of the disk and the stator, generates a force that carries the particles vertically along the wall of the product container into the expansion chamber. The particles lose their momentum and cascade down toward the center of the rotating disk owing to gravitational force. The cycle repeats itself, bringing about a thorough mixing unparalleled by any other powder-layering equipment. The degree of mixing depends on the fluidization air volume and velocity, the slit width, the bed size, and the disk speed. These variables, as well as liquid and powder application rates, atomization air pressure, fluidization air temperature, and degree of moisture saturation determine the yield and quality of pellets.

As mentioned earlier, the key process variable that determines the success of any pelletization process in centrifugal fluid-bed granulators is the degree of mixing, which is partly dictated by the radial velocity of the disk. At low radial velocities, the extent of mixing becomes inadequate, as indicated by the loss in the spiral rope-like motion of the particles. Thus, the rate at which the particles traverse the spray zone is prolonged and could potentially lead to excessive agglomeration. Caking is another serious problem encountered during powder layering at low radial velocities. At high radial velocities, the particle-to-particle and particle-to-wall frictional forces become intense with a very rapid pellet turnover. Generally, this condition leads to an uncontrollable, wobbly bed, resulting in severe particle attrition; that is, the breaking forces overcome the forces that contribute to particle growth through layering, and the pelletization process cannot proceed as intended. In such a situation, not only is a large amount of fines generated, but some of the attrited particles may agglomerate to form nuclei that are subsequently layered upon. Because the drug content of the pellets that contain inert starter seeds and those that use the newly formed nuclei are different, the process may create content uniformity problems. The optimum radial velocities of the disk are generally 3–8 m/s irrespective

of the granulator size (6). At the initial stages of the pelletization process, the radial velocity may be kept low and increased as the mass of the batch size increases. After the layering process is completed, the radial disk velocity is usually reduced to avoid particle attrition during the drying step.

Another parameter that plays a key role during layering is the disk clearance or slit width. In some centrifugal granulators, the slit width is fixed, and the fluidization air velocity can be varied only with a change in the fluidization air volume. In others, the slit width is variable and is adjusted to meet the processing requirements. As the disk

clearance is increased, the air velocity decreases, and pellet turnover is reduced. Conversely, as disk clearance decreases, the air velocity increases, resulting in a rapid pellet turnover. Therefore, for maximum process efficiency, the disk clearance is chosen not only to avoid loss of pellets through the gap between the disk and the vertical wall into the plenum and to minimize the loss of powder into the exhaust system but also to generate an air velocity that provides the desired degree of pellet turnover.

Aside from the rotary disk, the other unique feature of the centrifugal equipment is the spray method. During layering, the liquid is sprayed tangentially to and concurrent with particle movement. This feature is primarily responsible for the high yield that is typically obtained from a process involving this type of equipment. The distance the droplets travel before they impinge on the particles is short, and consequently, the droplets are picked up by the particles almost completely with little, if any, loss to the wall of the product chamber or because of spray drying, assuming that the other process variables are optimized.

In addition, powder and binder liquid delivery rates are critical parameters that must be carefully evaluated. Because the surface moisture/solvent determines the extent of binding between the forming pellets and the powder being introduced, the powder delivery and the liquid application rates should be adjusted to establish an equilibrium conducive to layering. It is essential that the powder delivery remains well-controlled during processing, whether airflow is mediated by suction

Fig. 4 Air distributor or orifice plate of a Wurster coater. (From Ref. 5.)

(negative pressure), as in the Glatt centrifugal granulators, or by positive air flow, as with the Freund CF granulators.

With a double-walled centrifugal granulator, the process is carried out with the inner wall in the open or closed position (Fig. 2) (7). With powder layering, the inner wall is closed so that simultaneous application of liquid and powder could proceed until the pellets have reached the desired size. The inner wall is then raised, and the spheres enter the drying zone. The pellets are lifted by the fluidization air up and over the inner wall back into the forming zone. The cycle is repeated until the desired residual moisture level in the pellets is achieved.

Scaling up of a layering process from the laboratory to production equipment is straightforward. As with all fluid-bed equipment, the most critical parameters that need to be met, in addition to the spiral rope-like motion of the particles, are the density of the particles and the droplet size within the spray zone. Because more than one spray gun is used in production equipment, it is imperative that the guns are positioned in such a way that optimum drying of the layered drug is attained before the pellets entering the next spray zone. Generally, the rate-limiting step in the process is saturation of the fluidization air by the application medium. Sometimes, it is likely that the spiral rope-like motion of the particles could be lost during scale up, and baffles must be inserted to enhance particle motion) (5).

As for formulation components, they also must meet certain requirements. Binder solutions must have a high binding capacity. Micronizing or finely milling the drug before layering improves the efficiency of the layering process significantly and provides morphologically smooth pellets that are suitable for film coating. However, in the majority of cases, micronization tends to impact flow and thus the delivery rate, a critical process parameter. Therefore, it is likely that during processing, powders may adhere to the sides of the hopper or the feed screw and may even form rat holes within the hopper. To improve the flow properties of the drug substance, glidants are incorporated into the powder before processing. Chemically, glidants could be hydrophobic or hydrophilic and are chosen based on the type of formulation selected.

Finally, the rheological properties of the binding liquid, the liquid application rate, and drying air temperature should be optimized to produce the desired product temperature. In addition, the powder should be delivered at a rate that maintains a balance between the surface wetness of the cores and powder adhesion. If the product bed temperature is high, powder is lost to the exhaust system. If it is too low, it leads to agglomeration and/or the formation of new nuclei that serve as cores for further layering. If that happens, content uniformity of the product

could be severely impacted. Therefore, the product temperature should be optimized to keep the particle population the same throughout the layering and subsequent drying steps.

SOLUTION/SUSPENSION LAYERING

The Wurster coating process, which was invented about 30 years ago, had evolved through elaborate design modifications and refinement into ideal equipment for the manufacture of pellets by solution/suspension layering. The high drying efficiency inherent in fluid-bed equipment, coupled with the innovative and efficient design features of the Wurster process, has allowed the machines to hold center stage in pharmaceutical processing technology. Not only have the manufacture and coating of pellets become routine and efficient, but scaling up of the process, which is key to the viability of any processing technique, has proved to be predictable and economically feasible.

The primary features that distinguish Wurster equipment from other fluid-bed equipment are the cylindrical partition located in the product chamber and the configuration of the air distributor plate, also known as the orifice plate (Figs. 3 and 4). The latter is configured to allow most of the fluidization or drying air to pass at high velocity around the nozzle and through the partition, carrying with it the particles that are being layered on. Once the particles exit the partition, they enter the expansion chamber, where the velocity of the air is reduced below the entrainment velocity, and the particles fall back to the area surrounding the partition (referred to as the down bed). The down bed is kept aerated by the small fraction of air that passes through the small holes on the periphery of the orifice plate. The particles in the down bed are transported horizontally through the gap between the air distributor plate and the partition by suction generated by the high air velocity that prevails around the nozzle and immediately below the partition. The volume of air that passes through the down bed outside the partition is just enough to generate modest particle movement. Because the spray direction is concurrent with particle movement, and particle motion is well-organized under optimum conditions, uniform layering of drug substances is consistently achieved. Because the partition height, that is, the gap between the partition and the orifice plate, controls the rate at which the particles enter the spray zone, it is an important variable that needs to be optimized for every batch size. For instance, at a given load size and fluidization air

volume, the partition height can be reduced or increased to provide either a well-controlled particle motion that produces the desired pellet movement or a bubbling down bed that leads to disorganized particle movement and inefficient process.

The disadvantage of the Wurster process is the inaccessibility of the nozzles. If the nozzles are clogged at any time during the layering process, the operation has to be interrupted, and the spray guns must be removed for cleaning. The problem can be alleviated by screening the formulation or by using a spray gun with a bigger nozzle. Another aspect of the process that is challenging when multiple nozzles are used is the potential overlap of adjacent spray zones. Although the position of the nozzle is fixed, the spray zone overlap can be minimized using the air cap at the end of the spray gun.

During scale up, the number of partitions in the product container is increased with an increase in batch size; the diameter of the partitions, however, is kept the same. The intent is to maintain the particle movement and processing dynamics that were established during the development phase when a single partition was used. The fluidization air volume is increased to compensate for the increase in the number of spray zones and consequently to create well-organized particle movement in all partitions. If the fluidization air volume is too high,

it is likely to produce a disorganized bed that in turn adversely affects the layering process. The fluidization air volume is also critical because it, rather than the size of the batch, dictates the liquid application rate.

Another piece of equipment that has been used to manufacture pellets by solution/suspension layering is the tangential spray or centrifugal granulator. An important parameter that needs to be established early in the process is quantity of starter seeds or cores charged into the machine that should, at the minimum, cover the nozzles during start-up; otherwise, the sprayed liquid droplets will either be sprayed onto the wall of the product container or become entrained in the fluidization air. The latter could lead to clogging of the filters, which would then not only increase the pressure differential across the filters and compromise the batch but also may complicate equipment cleanup. In either case, the yield, and probably the quality of the pellets, will be reduced dramatically. As the size of the forming pellets increases, the mass in the bed increases, and the fluidization air volume is continuously increased to provide optimum expansion and mixing of the product bed, as indicated by the spiral rope-like motion of the bed. If such particle movement is not achieved, the bed load may be excessive, and the process may have to be terminated. During layering, the product bed expands both vertically and horizontally, and

Fig. 5 Schematic representation of screw-fed extruders: (A) axial extruder. (B) radial extruder.

Fig. 7 Schematic representation of a ram extruder. (From Ref. 9.)

consequently a several-fold increase in batch weight can be realized in a single step.

During processing, all the components of the formulation are first dissolved or suspended in an appropriate quantity of application medium to provide a formulation with the desired viscosity and is then sprayed onto the product bed. The sprayed droplets immediately impinge on the starter seeds and spread evenly on the surface, provided the drying conditions and fluid dynamics are favorable. This is followed by a drying phase that renders dissolved materials to precipitate and form solid bridges that would hold the formulation components together as successive layers on the starter seeds. The process continues until the desired quantity of drug substance and thus the target potency of the pellets are achieved. The rate of particle growth is rather slow and is limited by the rate of solvent removal. Furthermore, the sprayed droplets must have the necessary rheological properties to spread evenly over the cores, as with coating processes. This must be followed immediately by a very rapid evaporation of the application medium. The evaporation rate should neither impair binder effectiveness nor lead to overwetting and subsequent agglomeration. Ideally, no new nuclei are formed, and the particle population remains the same; however, the sizes of the pellets increase as a function of time, and as a result, the total mass of the system also increases.

Although optimization of process variables is critical for the successful development of a pelletized product, pellets can only be manufactured routinely on a large scale if the formulation is not sensitive to slight variations in processing parameters. Therefore, it is imperative that the formulation characteristics are carefully identified and optimized, both qualitatively and quantitatively, during the development phase. These include drug solubility, type and concentration of binder, and viscosity of the solution/suspension. The working viscosity range usually determines the solid content of the formulation that can be sprayed successfully onto the starter seeds and forming pellets.

Fig. 8 Schematic representation of a spheronizer friction plate with a cross-hatch pattern.

Solution/suspension layering is usually used when the desired drug loading of the pellets is low because production of high-potency pellets from a low solids content formulation is not economically feasible. An important factor that needs to be considered when suspensions are used as opposed to solutions is the particle size of the drug. Micronized drug particles tend to provide pellets that are smooth in appearance, a property that is extremely desirable during subsequent film coating, particularly for controlled-release applications. If the particle size of the drug in the suspension is large, the amount of binder required to immobilize the particles onto the cores will be high, and, consequently, pellets of low potency are produced. The morphology of the finished pellets also tends to be rough and may adversely affect the coating process and the coated product. Moreover, because particles detach easily from the core they are being layered on owing to frictional forces, yield is usually low.

Although it is possible to manufacture pellets from a formulation that does not contain binders, almost invariably, the layers of drug applied tend to delaminate or break off from the cores in the later stages of the layering process or in the subsequent drying step. Therefore, binders are consistently used during solution/suspension layering to impart strength to the pellets. They are usually low-molecular-weight polymers that are compatible with the drug substance. They should not increase the viscosities of the formulations appreciably and should not, unless

intended to do so, modify the release characteristics of the pellets.

EXTRUSION–SPHERONIZATION

Extrusion–spheronization as a pelletization technique was developed in the early 1960s and since then has been researched and discussed extensively. Interest in the technology is still strong, as witnessed by the extent of coverage of the topic in scientific meetings and symposium proceedings, as well as in the scientific literature. The technology is unique in that it is not only suitable for the manufacture of pellets with a high drug loading but it also can be used to produce extended-release pellets in certain situations in a single step and thus can obviate the need for subsequent film coating.

Extrusion–spheronization is a multistep process involving a number of unit operations and equipment. However, the most critical pieces of processing equipment that, in effect, dictate the outcome of the overall process are the extruders and the spheronizers (8).

A variety of extruders, which differ in design features and operational principles, are currently on the market and can be classified as screw-fed extruders, gravity-fed extruders, and ram extruders.

Screw-fed extruders have screws that rotate along the horizontal axis and hence transport the material horizontally; they may be axial or radial screw extruders (Fig. 5). Axial extruders, which have a die plate that is positioned axially, consist of a feeding zone, a compression zone, and an extrusion zone. The product temperature is controlled during extrusion by jacketed barrels. In radial extruders, the transport zone is short, and the material is extruded radially through screens mounted around the horizontal axis of the screws.

Gravity-fed extruders include the rotary cylinder and rotary gear extruders, which differ primarily in the design of the two counter-rotating cylinders (Fig. 6). In the rotary-cylinder extruder, one of the two counter-rotating cylinders is hollow and perforated, whereas the other cylinder is solid and acts as a pressure roller. In the so-called rotary-gear extruder, there are two hollow counter-rotating gear cylinders with counterbored holes.

In ram extruders, a piston displaces and forces the material through a die at the end (Fig. 7). Ram extruders are preferred during formulation development because they are designed to allow for measurement of the rheological properties of formulations (9–11).

Because extruders were initially developed to serve industries other than the pharmaceutical industry, they were

Fig. 9 Shape transitions during a spheronization process.

designed without GMP considerations. Therefore, changes are made to ensure pharmaceutical regulatory compliance, including qualification requirements. At the minimum, all the parts of the extruder that come in contact with the product must be of high-quality stainless steel, and the construction must be such that cleaning requirements are easily met. Whenever possible, the machine should permit easy monitoring and documentation of all critical process parameters such as pressure at the die plate, product temperature, power consumption or torque of the drive unit, and rotational speed of the screw. Some of the GMP requirements surrounding extruders have been

highlighted in an article that described a qualification procedure for an extruder that is suitable for the manufacture of clinical samples (12).

The extrusion/spheronization process was first introduced to the pharmaceutical industry in 1964 with the invention of the marumerizer (13). Since then, significant improvements have been made to the machine, and currently well-designed marumerizers of different sizes are commercially available. A marumerizer or spheronizer consists of a static cylinder or stator and a rotating friction plate at the base. The stator can be jacketed for temperature control. The friction plate, which has a grooved surface, is the most critical part of the equipment that initiates the spheronization process. A typical friction plate has a crosshatch pattern, where the grooves intersect at a 90° angle, as shown in Fig. 8. The groove width is selected based on the desired pellet diameter. Usually, groove diameters 1.5–2 times the target pellet diameter are used. The diameter of the friction plate is approximately 20 cm for laboratory-scale equipment or up to 1.0 m for production-scale units. The rotational speed of the friction plate is variable and ranges from 100 to 2000 rpm, depending on the diameter of the unit.

A new variation of spheronizers that was introduced into the market are the so-called air-assisted spheronizers. Basically, they are similar to the standard spheronizers except that they are designed to permit a conditioned air stream to pass from beneath the rotating disk through the gap or slit between the cylindrical wall and the

rotating friction plate into the product bed. The addition of such a feature presumably improves pellet turnover and brings about a spiral rope-like motion that facilitates spheronization.

Axial-type extruders tend to produce extrudates with slightly higher densities. Twin-screw extruders have better material transport characteristics and higher capacity or throughput than do single screw extruders. Radial-type extruders have higher throughput but produce less dense extrudates than those obtained from axial-type extruders. The product temperature in radial extruders increases very little during the extrusion process, probably because of a shorter compression zone and shorter die opening depth. Absence of heat build-up during extrusion leads not only to well-controlled spheronization process but also allows for the processing of thermolabile drug substances.

Although the extrusion step is a continuous process with a very high throughput, the subsequent steps (spheronization, drying, and sizing) are batch processes, and thus are rate limiting. As a result, the overall extrusion–spheronization process is a batch rather than a continuous process. However, a semicontinuous process can be implemented by having an extruder feed, alternatively, into two spheronizers. As one of the spheronizers is spheronizing the extrudates, the other discharges the formed pellets and is recharged with fresh extrudates. The process is then repeated as the roles of the spheronizers are reversed alternately.

In a batch process, a defined quantity of extrudate is fed into the spheronizer from the top, and the spheronized

particles are discharged by centrifugal force via a discharge chute located at the base of the stator or vertical wall of the cylinder. The extrudates are spheronized by interparticle collisions and particle-to-wall frictional forces. The various stages of the spheronization process are shown in Fig. 9. The spheronizing time is usually 2–15 min, depending on the formulation characteristics. Processing time remains constant, provided the composition of the extrudate, including the water content, is kept constant. Because relatively large amounts of water or solvent are incorporated into the formulation, the final pellets contain significant quantities of residual moisture or solvent and are oven-dried or dried in a fluid-bed dryer before further processing. A sizing step might be necessary to separate the fractions if the particle size distribution is wider than intended. In general, the pellets are spherical and have a narrow particle size distribution. The most critical process parameters in the spheronization step that influence the yield and quality are the design of the grooves and rotational speed of the friction plate and the residence time in the spheronizer.

In an extrusion–spheronization process, formulation components such as fillers, lubricants, and pH modifiers play a critical role in producing pellets with the desired attributes. The granulated mass must be plastic and sufficiently cohesive and self-lubricating during extrusion. During the spheronization step, it is essential that the extrudates break at appropriate length and have sufficient surface moisture to enhance formation of uniform spherical pellets.

The degree of liquid saturation of the granulation is another critical factor that needs to be optimized. Granulations containing low moisture content may generate extrudates that produce large quantities of fines during the spheronization step. If the moisture level is too high, the extrudates may adhere to each other and form bundles of strands that cannot be processed further. Therefore, the extrudates must have sufficient mechanical strength to form strands during the extrusion but must also be easily broken into uniform rods during spheronization to provide pellets with a narrow particle size distribution. Generally, the liquid content of the wet powder mixture is approximately 20–30% (w/w). Solvents such as ethanol or mixtures of water and ethanol may be used as granulating liquids when pure water cannot be used for stability or solubility reasons.

Excipients play a more significant role during extrusion–spheronization than during with any other pelletization process (14). They facilitate extrusion and determine the sphericity of the wet pellets; they also impart strength and integrity to the pellets. Microcrystalline cellulose is one of the most widely investigated

excipients. It is used as filler and a spheronization aid, regulating the water content and distribution in the granulation. In effect, it modifies the rheological properties of the formulation and imparts plasticity to the pellets. Lactose is another excipient that has been studied extensively and used to evaluate the factors that govern the mechanism of pellet formation by extrusion–spheronization.

In contrast to layering processes, extrusion–spheronization can be used to manufacture pellets with sustained-release characteristics without the application of functional membranes to control release. For instance, matrix-type pellets can be produced with the help of mixture of microcrystalline cellulose and sodium carboxymethylcellulose (15, 16). Organic acids can be incorporated into the pellet matrix to stabilize sensitive drug substances or modify the release characteristics, especially if the solubility of the drug substance being formulated is pH-dependent (17). Although water or other granulation media act as lubricating agents during extrusion, lubricants are sometimes incorporated to improve processing.

Finally, it is not surprising that the drug substance itself plays an important role in the pelletization process, particularly at high drug loading. Physicochemical properties such as particle size, polymorphism, wettability, and solubility determine not only the amount of active ingredient that can be incorporated in the formulation but also the quality and thus the shape and surface smoothness of the final pellets.

Because extrusion–spheronization is a very complex manufacturing process that depends on a number of formulation and processing factors (Table 1), it has been studied extensively. Some of these studies used multifactorial statistical designs to determine the significance of the various factors identified above (12, 18–20). Despite the extensive work that had been done, additional research is still ongoing as demonstrated by the number of publications in various scientific journals (21–28).

SPHERICAL AGGLOMERATION

Spherical agglomeration, or balling, is a pelletization process in which powders, on addition of an appropriate quantity of liquid or when subjected to high temperatures, are converted to spherical particles by a continuous rolling or tumbling action. Spherical agglomeration can be divided into two categories—liquid-induced and melt-induced agglomerations. Over the years, spherical agglomeration has been carried out in horizontal drum pelletizers, inclined

dish pelletizers, and tumbling blenders; more recent technologies use rotary fluid-bed granulators and high-shear mixers. Although spherical agglomeration has been practiced routinely in the iron ore and fertilizer industries, its application in the pharmaceutical industry is marginal at best. Nevertheless, the process is one of the most thoroughly investigated pelletization processes, and as a result, a number of mechanisms describing the various phases of pellet formation and growth during spherical agglomeration have been proposed (29).

During liquid-induced agglomeration, liquid is added to the powder before or during the agitation step. As powders come in contact with a liquid phase, they form agglomerates or nuclei, which initially are bound together by liquid bridges. These are subsequently replaced by solid bridges, which are derived from the hardening binder or any other dissolved material within the liquid phase. The nuclei formed collide with other adjacent nuclei and coalesce to form larger nuclei or pellets. The coalescence process continues until a condition arises in which bonding forces are overcome by breaking forces. At this point, coalescence is replaced by layering, whereby small particles adhere on much larger particles and increase the size of the latter until pelletization is completed (30, 31). If the surface moisture is not optimum, some particles may undergo nucleation and coalescence at different rates and form different sizes of nuclei admixed with the larger pellets. As a result, spherical agglomeration tends to produce pellets with a wide particle size distribution.

The rate and extent of agglomerate formation depend, in part, on formulation variables such as particle size and solubility of the powder, the degree of liquid saturation, and the viscosity of the liquid phase. The moisture content is particularly critical because it determines whether nucleation occurs to initiate pelletization or whether the nuclei formed have the necessary plasticity to bring about coalescence after collisions between two nuclei. Furthermore, layering of fine particles on the larger nuclei or pellets occurs only if the surface moisture is above the critical level. The rate and extent of agglomerate formation also depend on processing variables, which are specific to a given piece of equipment. In the case of drum pelletizers, drum speed, residence time, load size, and angle of inclination, relative to the horizontal, are critical process variables that need to be optimized. Variables critical to a spherical agglomeration process using centrifugal fluid-bed granulators are disk speed, load size, residence time, fluidization air volume and temperature, and disk clearance (32–43).

Melt-induced agglomeration processes are similar to liquid-induced processes except that the binding material is a melt. Therefore, the pellets are formed with the help of

congealed material without having to go through the formation of solvent-based liquid bridges (44–55).

SPRAY DRYING AND SPRAY CONGEALING

Spray drying and spray congealing, known as globulation processes, involve atomization of hot melts, solutions, or suspensions to generate spherical particles or pellets. The droplet size in both processes is kept small to maximize the rate of evaporation or congealing, and consequently the particle size of the pellets produced is usually very small. During spray drying, drug entities in solution or suspension are sprayed, with or without excipients, into a hot air stream to generate dry and highly spherical particles. As the atomized droplets come in contact with hot air, evaporation of the application medium is initiated. This drying process continues through a series of stages whereby the viscosity of the droplets constantly increases until finally almost the entire application medium is driven off and solid particles are formed. Generally, spray-dried pellets tend to be porous. For a thorough discussion on spray drying technology, see Masters (56).

During spray congealing, a drug substance is allowed to melt, disperse, or dissolve in hot melts of waxes, fatty acids, etc., and sprayed into an air chamber, where the temperature is below the melting temperatures of the formulation components, to provide spherical congealed pellets under appropriate processing conditions. A critical requirement in a spray-congealing process is that the formulation components have well-defined, sharp melting points or narrow melting zones. Because the process does not involve evaporation of solvents, the pellets produced are dense and nonporous. See Atilla and Suheylo (57) for a detailed description of the formulation and processing requirements of spray congealing as a pelletization technique.

CRYOPELLETIZATION

Cryopelletization is a process whereby droplets of a liquid formulation are converted into solid spherical particles or pellets by using liquid nitrogen as the fixing medium. The technology, which was initially developed for lyophilization of viscous bacterial suspensions, can be used to produce drug-loaded pellets in liquid nitrogen at -160°C . The procedure permits instantaneous and uniform freezing of the processed material owing to the rapid heat transfer that occurs between the droplets and liquid nitrogen. The pellets are dried in conventional freeze dryers. The small

size of the droplets and thus the large surface area facilitate the drying process. The amount of liquid nitrogen required for manufacturing a given quantity depends on the solids content and temperature of the solution or suspension being processed. It is usually between 3 and 5 kg per kilogram of finished pellets.

The equipment consists of a container equipped with perforated plates at the bottom. Immediately below the plates at a predetermined distance is a reservoir of liquid nitrogen, in which a conveyor belt with transport baffles is immersed. The conveyor belt has a variable speed and can be adjusted to provide the residence time required for freezing the pellets. The perforated plates generate droplets that fall and freeze instantaneously as they come in contact with the liquid nitrogen below. The frozen pellets are transported out of the nitrogen bath into a storage container at -60°C before drying. Equipment of different size, ranging from laboratory scale to production size, is available commercially. (See Refs. (58, 59) for a detailed description.)

The most critical step in cryopelletization is droplet formation, which is influenced not only by formulations-related variables such as viscosity, surface tension, and solids content but also by equipment design and the corresponding processing variables. The diameter and design of the shearing edge of the holes on the container plates are critical. For instance, the diameter of the holes determines the flow rate, which, in turn, is governed by the viscosity of the formulation. The diameter of the holes also influences the size and shape of the pellets. The smaller the holes, the smaller the pellets produced.

The shape of the droplets depends in part on the distance the droplets travel before contacting the liquid nitrogen. The distance has to allow sufficient time for the formulation of spherical droplets as they contact the liquid nitrogen. When all processing parameters are carefully characterized and optimized, smooth, spherical pellets can be routinely manufactured. In cases, in which the desired pellet diameter is less than 2 mm, the liquid nitrogen is stirred to prevent agglomeration.

Solutions or suspensions suitable for cryopelletization have high solids content and low viscosities. Another important property is the surface tension of the liquid formulation, which partly determines the pellet size. The addition of a surfactant to the formulation reduces the surface tension and results in smaller particle size. Pellet size also depends on the properties of the drug substance.

Immediate-release formulations typically consist of the drug substance, fillers such as mannitol and lactose and binders such as gelatin, gelatin hydrolysates, and polyvinylpyrrolidone. Cross-linked biopolymers based on collagen derivatives are used for sustained-release pellets.

See Refs. (59, 60) for a detailed discussion on the formulation and processing variables.

MELT SPHERONIZATION

Melt spheronization is a process whereby a drug substance and excipients are converted into a molten or semimolten state and subsequently shaped using appropriate equipment to provide solid spheres or pellets. The process requires several pieces of equipment such as blenders, extruders, cutters (known as pelletizers in the plastics industry), and spheronizers. The drug substance is first blended with the appropriate pharmaceutical excipients, such as polymers and waxes, and extruded at a predetermined temperature. The extrusion temperature must be high enough to melt at least one or more of the formulation components. The extrudate is cut into uniform cylindrical segments with a cutter. The segments are spheronized in a jacketed spheronizer to generate uniformly sized pellets. The spheronization temperature needs to be high to partially soften the extrudate and facilitate deformation and eventual spheronization (61). Depending on the characteristics of the formulation ingredients, pellets that exhibit immediate- or sustained-release characteristics can be manufactured in a single step. The pellets produced are unique in that they are monosize, a property unmatched by any other pelletization technique. However, the process is still in the development stage, and additional work is needed before the process becomes a viable pelletization technique.

PEPTIDES AND PROTEINS—ORAL ABSORPTION

Eugene J. McNally

Jung Y. Park

Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, Connecticut, U.S.A.

INTRODUCTION

Rapid developments in biotechnology have posed new challenges for pharmaceutical research scientists to develop peptide (>3 amino acids) and protein drugs. Although these peptide and protein drugs are highly potent and specific in their physiological actions, they are in general difficult to administer orally. The reason is that most peptide and protein drugs are very unstable in the gastrointestinal (GI) tract and show poor oral absorption because of their size and hydrophilic nature (there are specific exceptions, e.g., cyclosporine). Although each nonparenteral delivery route has its own advantages and disadvantages, based on the available published data and the known permeability of mucosal membranes, it may be possible to rank them as the preferred route for the delivery of peptide and protein drugs. It appears that the nasal cavity is the preferred route for the delivery of peptide and protein drugs, followed by the vaginal, pulmonary, oral, and transdermal routes, respectively. It is common knowledge that peptide and protein drugs are easily hydrolyzed and digested by acids and enzymes in the GI tract. In addition, these drugs usually show low bioavailability because of their poor membrane permeability in the GI tract.

To deliver peptide and protein drugs orally, it is necessary to protect them from the hostile GI environment. Many strategies, such as coadministration with nonspecific protease inhibitors as well as the use of chemical modification approaches to improve resistance to enzymatic degradation, have been reported in the scientific and patent literature. In recent years, a number of drug-delivery companies specializing in protein delivery have emerged. A number of these companies are attempting to apply formulation approaches such as liposomes or microspheres to protect protein drugs from enzymatic degradation in the GI tract or using site-specific delivery to the colon or rectum to bypass the harsh GI environment. In addition, to increase the GI absorption of the peptide and protein drugs, absorption enhancers as well as carriers or prodrug approaches are being explored.

The purposes of this article are sixfold: 1) to review the GI tract as it relates to the absorption of drugs; 2) to review briefly the structures of peptides and proteins; 3) to review the enzymatic and physical barriers for intestinal permeability of peptides and proteins; 4) to review the absorption of amino acids, peptides, and proteins across the GI tract; 5) to review the kinds of absorption enhancers and how they work; and 6) to review possible ways to improve the absorption of poorly bioavailable peptide and protein drugs.

GASTROINTESTINAL PHYSIOLOGY RELEVANT TO ABSORPTION

A rational approach to understanding the GI absorption of peptides and proteins requires some knowledge of the GI tract such as morphology, function of different components of the cells, geometry, ultrastructure, biochemical processes, hydrodynamics in the intestinal lumen, and transport mechanisms.

The Digestive System

The digestive system consists of the canal from the mouth to the anus (oropharynx, esophagus, stomach, small intestine, and large intestine) and associated organs (salivary glands, liver, gallbladder, and pancreas) (Fig. 1). The small intestine is divided into three parts, the duodenum, jejunum, and ileum, and is the primary site of absorption for most drugs. The large intestine, which is also called the colon, is divided into the caecum, ascending colon, transverse colon, descending colon, sigmoid colon, rectum, and anus. The salivary glands, liver, gallbladder, and pancreas deliver digestive secretions and help digestion and absorption of peptide and protein drugs.

Stomach

The inner surface of the stomach consists of well-defined tissue layers: the muscle and the submucosal and mucosal layers. The absorption function of stomach is minimal

Fig. 1 The human digestive system. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

owing to the limited surface area, lack of villi, thick mucosal layer, and short residence time. The epithelium of the gastric mucosa secretes hydrochloric acid, pepsin, intrinsic factor, and bicarbonate (1). The low pH of gastric juice generated by hydrochloric acid causes protein denaturation (unfolding), which results in increased exposure of peptide bonds to pepsin, which breaks down the proteins into peptides. However, hydrolysis in the stomach is incomplete because pepsin can only break peptide bonds between specific amino acids.

Small intestine

Most enzymatic hydrolysis of the macromolecules in food occurs in the small intestine. The small intestine is approximately 5 m long with a radius of approximately 2 cm, and is divided into three anatomical regions: the duodenum (the first 25 cm), the jejunum (the second 2.0 m), and the ileum (the last 2.75 m) (1). The intestinal membrane wall consists of four basic layers: the mucosa, submucosa, muscularis, and serosa.

The mucosal layer, comprising the luminal surface of the small intestine, is responsible for the digestive and absorptive functions of the small intestine. The mucosal surface area is much larger than predicted for a simple cylinder. Circular folds account for this amplification. The mucosal surface area is extended further by fingerlike projections called villi and depressions called crypts. The villi are 0.5–1.0 mm in height. Each villus and crypt is lined by epithelial cells that are covered with many closely packed microvilli that project into the intestinal lumen. If the small intestine is viewed as a simple cylinder, its mucosal surface area would be on the order of half of a square meter. However, in reality, the mucosal surface

area of the small intestine is approximately 250 square meters, comparable with size of a tennis court.

Mucous surface: The mucosa of the small intestine consists of three layers (Fig. 2): an absorptive layer, a continuous single sheet of columnar epithelium; the lamina propria, a layer heterogeneous in composition and cell type; and the muscularis mucosa, a muscular layer separating the mucosa and submucosa.

The lamina propria consists primarily of connective tissue and supports the epithelium lining. There is ample evidence that the lymphoid cells and associated structures of the lamina propria play an important role immunologically. Small lymphoid nodules are present in the upper small intestine, whereas large organized aggregates of lymphoid tissue (Peyer's patches) are present in the ileum. The lymphoid cells, nodules, and Peyer's patches of the lamina propria, along with the intraepithelial lymphocytes, establish the so-called gut-associated lymphoid tissue (GALT), which is a major subgroup of the immune system and makes up as much as 25% of the gastrointestinal mucosa.

A one-cell thick sheet of epithelial cells covers the surfaces of the villi and lines of crypts. Some of the cell types identified in the epithelial lining of the small intestine are enterocytes (digestion and absorption), goblet cells (mucus secretion), endocrine cells (hormone secretion), and M cells (absorption of food and antigens).

Absorptive cells: Absorptive cells (commonly called enterocytes or brush border cells) are the most prevalent type of cells on the tips of villi and are the most important for absorption (Fig. 3). In humans, these cells are 20–30 μm in height and 8–10 μm in width. The mucosal surface of this cell is characterized by the presence of microvilli (the brush border, approximately 1.0 μm in height and 0.1–0.2 in width). The microvilli look something like a brush, as shown in Fig. 3. For this reason, the microvillus border of intestinal epithelial absorptive cells is called the brush border. The microvillus plasma membrane has a trilaminar structure (70–90° A thick) composed of proteins, neutral lipids, phospholipids, and glycolipids. An integral and dynamic part of the plasma membrane is the glycocalyx, which is a uniform layer of filamentous glycoproteins (Fig. 4) (2). This glycocalyx layer has a negative charge at physiological pH primarily owing to the presence of sialic acids at the terminal position in the carbohydrate chain. The microvillus and its glycocalyx are viewed as the digestive-absorptive unit of the enterocyte. The plasma membrane of microvilli has an unusually high protein-to-lipid ratio, owing to the presence of specialized proteins possessing enzymatic, receptor, and transport properties. This microvillus plasma membrane contains a number of

Fig. 2 Schematic depiction of two-section villi and a crypt to illustrate the small intestine mucosa. Also shown is an aqueous boundary layer located at the intestinal lumen and membrane interface. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

enzymes (peptidases) involved in the hydrolysis of peptides. In addition, proteins responsible for the cotransport of sodium and amino acids have been found in the microvillus plasma membrane. Receptor proteins specific for certain substances have been found on the microvilli of enterocytes in different regions of the small intestine. For example, the receptors for the intrinsic factor vitamin B₁₂ complex are present in the microvilli of ileal enterocytes but are not found on jejunal cells. This is why vitamin B₁₂ is absorbed exclusively from the ileum. Vitamin B₁₂ has been explored as a delivery system for peptide and proteins by covalently conjugating vitamin B₁₂ to peptides (leuteinizing hormone-releasing hormone, LHRH) or proteins (bovine serum albumin, BSA) (3).

The absorptive cell basolateral membrane rests on the lamina propria. The basolateral membrane is different from the apical membrane. It has a low protein-lipid ratio and is thinner and more permeable than the apical membrane. In addition, different enzymes are present at the basolateral membrane compared with the apical membrane. Adjacent

cells are connected by a junctional complex called the tight junction. This tight junction is important because it represents one possible route of intestinal absorption, known as the paracellular route. The other major route of absorption is across the cell, also known as the transcellular route. These routes will be discussed later.

Aqueous boundary (diffusion) layer: The aqueous boundary layer (often referred to as the stagnant, unstirred, or aqueous diffusion layer) is an important hydrodynamic barrier that a drug must traverse before reaching the surface of the mucosal membrane (4). Before a molecule in the intestinal lumen passes through the membrane, it must first cross the aqueous boundary layer located at the intestinal lumen and membrane interface (Fig. 2). The liquid in this layer, in reality, is not static, as the term “unstirred” implies, but represents a film at the surface where diffuse and natural convective mixing occurs. This unstirred layer can be a rate-limiting step for the absorption of hydrophobic molecules. However, hydrophilic molecules such as peptides will diffuse through the

Fig. 3 Schematic depiction of intestinal epithelial absorptive cells. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

aqueous boundary layer with less resistance. The effective thickness of the aqueous boundary layer is thinner around the tips of the villi and thicker and less stirred in the valleys of the villi. The existence of the aqueous boundary layer is physically sound and experimentally demonstrable (5).

Luminal and membrane metabolism of peptides and proteins: In meaningful studies on peptide and protein drug absorption in the small intestine, it is prerequisite to distinguish among cavital, membrane contact, and intracellular drug metabolism (4). Cavital metabolism takes place in the lumen of the small intestine by enzymes such as trypsin, chymotrypsin, carboxypeptidase, and elastase, which are secreted by the pancreas. Membrane contact metabolism is carried out by aminopeptidases localized on the brush border membrane. Intracellular metabolism occurs inside of the cells. The known intracellular enzymes are cytoplasmic peptidases, prolidase, dipeptidase, and tripeptidase (1). A more detailed discussion of this topic is presented in "Intestinal Absorption Barriers," later.

Intestinal blood flow: The mechanistic relationship among intestinal blood flow and absorption, secretion, and metabolic activity of the intestinal mucosa is unclear.

However, there is evidence that impaired intestinal blood flow rate correlates with a decrease in drug absorption rate. It has been postulated that reduced blood flow slows down the absorption rate by: 1) decreasing the effective concentration gradient across the epithelial layer for passively absorbed molecules, by not rapidly carrying the molecule away, and 2) by lowering oxygen supply to the absorption cells needed to maintain the active transport mechanism for absorption.

In general, when molecules transport through the epithelium cell layer directly into the mesenteric blood draining the small intestine, the total mass transfer resistance may be described by the sum of resistance for barriers (aqueous boundary layer in front of the membrane, the membrane itself, and the aqueous boundary layer in blood side) in series (6):

$$\frac{1}{P_{app}} = \frac{1}{P_{aq}} + \frac{1}{P_{membrane}} + \frac{1}{P_{blood}} \quad (1)$$

where P_{app} is apparent permeability coefficient; P_{aq} is permeability coefficient of the aqueous boundary layer; $P_{membrane}$ is permeability coefficient of the membrane; and

Fig. 4 Schematic depiction of glycocalyx. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

P_{blood} is permeability coefficient of the blood boundary layer.

When the permeabilities of the aqueous boundary layer and membrane are relatively large, reduced blood flow becomes the rate-limiting step. For example, the apparent permeability coefficient is approximately 85% controlled by blood flow when P_{aq} and P_{membrane} are each approximately 10 times greater than P_{blood} .

Large intestine (colon)

The large intestine (or colon) is divided into five parts: 1) the caecum, or opening into the colon; 2) the ascending colon, or second section of the large intestine; 3) the transverse colon; 4) the descending colon; and 5) the sigmoid colon, which is at the end of the colon, ending in the rectum (Fig. 1). The large intestine is approximately 1.5 m long, and its proximal diameter is approximately 2 inches. The wall of the large intestine is divided into four layers, exactly the same as the small intestine: the serosa, muscularis externa, submucosa, and mucosa. However, the mucosa does not contain villi, and the microvilli and the cells are much less dense than those in the small intestine. It also contains a large number of bacteria, which digest food residues into caloric substance that are subsequently absorbed. The total bacteria count in the large intestine is higher than that in the stomach and small intestine. Attempts have been made to deliver peptide and protein drugs to the colon by coating the drug particles with copolymers that are sensitive to bacterial azo-reductases (7).

In addition, the colon has recently received considerable attention as a possible delivery site for peptide and protein drugs because of low proteolytic activity in this region of the GI tract.

Rectum

The rectum is the terminal 15 to 19 cm of the large intestine. The mucous membrane of the rectum consists of a layer of cylindrical epithelial cells, without villi. The pH in the rectum is between 7.2 and 7.4. The surface area is only 200–400 cm². Drug absorption takes place through three veins of the submucous plexus. Superior rectal veins enter into the portal veins and deliver drugs to the liver. However, the inferior and middle rectal veins connect with the inferior vena cava and thus bypass the liver. This may provide an advantage for the delivery of some peptide and protein drugs through the rectal membrane, thus bypassing the liver.

STRUCTURAL AND FUNCTIONAL ASPECTS OF PEPTIDES AND PROTEINS

In addition to understanding the morphology and function of the GI tract, it is also important to have a thorough understanding of the physical/chemical properties of peptides and proteins to rationally formulate them for successful oral delivery. An extensive review is beyond the scope of this article [see other sections in this text and a recent text on formulation and delivery of proteins (8)]. Instead, a brief description of peptides and proteins is provided that focuses on those characteristics that give rise to the unique biological activity of these molecules. Peptides are formed by loss of water from the NH₂ and COOH groups of adjacent amino acids; they are referred to as di-, tri-, tetra- (etc.) peptides depending on the number of amino acids composing them. The term oligopeptides refers to peptides that have fewer than eight amino acids, whereas polypeptide refers to those peptides that contain approximately eight or more amino acids. An amino acid unit in a polypeptide is called a residue. Polypeptides that contain from approximately 50 (molecular weight ≈6000) to more than 8000 amino acid residues (molecular weight ≈1,000,000) are called proteins (9). Each protein molecule is a polymer of α-amino acids linked together in a sequential manner by peptide bonds. Although more than 100 amino acids occur in nature, particularly in plants, only 20 are commonly found in most proteins.

Proteins are one of the major naturally occurring organic compounds, and they constitute much of animal and plant tissue. The word protein comes from the Greek

word *proteios*, meaning first place, because proteins are thought to be the most important part of living matter. They are instrumental in almost everything cells do. Proteins are the most abundant components of cells. They account for more than 50% of the dry weight of most cells (9). They serve as antibodies, enzymes, hormones, transport mediators, and structural elements.

Unlike traditional small molecular weight chemical drugs, peptide and especially protein drugs are highly complex molecules that possess primary, secondary, tertiary, and quaternary structures. The primary structure refers to the linear amino acid sequence of a peptide or protein. The secondary structure refers to the way in which segments of the peptide backbone orient into regular patterns such as a α -helix or β -sheet. The tertiary structure refers to the native conformation that is formed by the folding of the secondary structures to a compact, tightly folded structure to reach the most thermodynamically stable state. Quaternary structure occurs when a protein molecule consists of two or more polypeptide chains (10).

A protein's biological function depends on its unique conformation. This conformation is a consequence of the specific linear sequence of the amino acids that makes up the polypeptide chain (primary structure) and the specific three-dimensional structure (conformation) the protein molecule adopts. In general, nonpolar residues tend to fold into the center of the structure to get away from water, whereas the polar residues tend to stay on the surface in contact with water. To maintain the biological activity of the protein drug, this unique higher-order physical structure must be preserved during passage through the GI tract and upon absorption. Subtle changes in the chemical and physical structure can lead to a loss of biological activity.

INTESTINAL ABSORPTION BARRIERS

Enzymatic Barriers

Most dietary proteins are known not to be absorbed in humans as intact forms. Instead, they are usually broken down into amino acids or di- and tripeptides first in the GI tract. The stomach secretes pepsinogen, which is converted to the active protease pepsin by the action of acid. Pepsins, which are most active at pH 2 to 3, hydrolyze partially digested dietary proteins. The partially digested dietary proteins are further broken down by proteolytic enzymes (peptidases) produced by the pancreas and secreted in the duodenum of the small

intestine. The peptidases that break the internal peptide linkages are known as endopeptidases, whereas those that attack the terminal, or end, groups of amino acids are called exopeptidases. The endopeptidases are trypsin, chymotrypsin, and elastase, and the only exopeptidase enzymes are carboxypeptidases (1). All four enzymes (trypsin, chymotrypsin, carboxypeptidases, and elastase) are secreted by the pancreas as inactive, proenzyme forms of trypsinogen, chymotrypsinogen, procarboxypeptidases, and proelastase. The enzyme enterokinase (also called enteropeptidase) within the lumen of the small intestine converts trypsinogen to trypsin. Then, trypsin converts chymotrypsinogen, procarboxypeptidases, and proelastase to chymotrypsin, carboxypeptidases, and elastase, respectively (1). These enzymes, whose function in vivo is to break down food proteins into amino acids that can be then absorbed and turned into energy, will also degrade a protein drug. It is important to understand the function and sites of secretion of these enzymes so that strategies to protect protein drugs from degradation can be developed.

These four peptidases secreted from the pancreas convert proteins and polypeptides to oligopeptides. The luminal degradation is up to 20% of the total degradation in a given small intestinal segment (11). The rest of the degradation occurs on contact with the brush border membrane or after entry into the cell. Brush border peptidases such as amino oligopeptidase, amino peptidase, and dipeptidyl aminopeptidase then break down the oligopeptides to amino acids (up to 70%) and di- and tripeptides (up to 30%) (1). The di- and tripeptides that cross the brush border membrane are converted to single amino acids by the intracellular enzymes known as cytoplasmic peptidases, prolidase, dipeptidase, and tripeptidase (1).

The above-mentioned enzymatic barriers must be overcome to improve oral absorption of peptide and protein drugs from the GI tract. This may be possible to achieve to some extent by the coadministration of proteolytic enzyme inhibitor or by chemical modification of peptides or proteins and by other formulation approaches (see "Intestinal Absorption of Amino Acids, Peptides, and Proteins," later).

Physical Barriers

Absorption barriers are related to the permeability of drug molecules across the gastrointestinal membrane including the colonic membrane. There are two distinct mechanisms for molecules to cross the membrane: via paracellular transport and transcellular transport (Fig. 5) (12). Paracellular transport involves only passive diffusion where the molecules pass through the tight junctions between the epithelial cells. In contrast, transcellular transport can occur

Fig. 5 Routes for the transport of drugs across the GI epithelial cells. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

by passive diffusion as well as by active transport, or endocytosis. In general, the hydrophilic molecules diffuse predominantly through the paracellular route, whereas the lipophilic molecules traverse predominantly through the epithelial cells.

Transcellular transport

Three processes are involved in transcellular transport across the intestinal epithelial cells: simple passive trans-

port, passive diffusion together with an efflux pump, and active transport and endocytosis. Simple passive transport is the diffusion of molecules across the membrane by thermodynamic driving forces and does not require direct expenditure of metabolic energy. In contrast, active transport is the movement of molecules across the membrane resulting directly from the expenditure of metabolic energy and transport against a concentration gradient. Endocytosis processes include three mechanisms: fluid-phase endocytosis (pinocytosis), receptor-mediated endocytosis, and transcytosis (Fig. 6). Endocytosis processes are covered in detail in “Absorption of Polypeptides and Proteins,” later.

The mechanism whereby drugs are absorbed from the GI tract is complex. Understanding the intestinal transport mechanism is crucial to the prediction of oral drug absorption. The physical model (13–15) utilizes the basic principles of thermodynamics and mass transport. The physical model for the simultaneous passive and active membrane transport of drugs in the intestinal lumen is depicted in Fig. 7. The bulk aqueous solution with an aqueous boundary layer on the mucosal side is followed by a series of heterogeneous membranes consisting of parallel lipoidal and aqueous channel pathways for passive and active transport. Thereafter, a sink on the serosal side follows.

The rate of disappearance of a drug from the intestinal lumen and appearance in the blood is given by:

$$\frac{dC_b}{dt} = -\frac{A}{V}P_{app}(C_b - C_{blood}) \tag{2}$$

when there is no accumulation of drug in the blood side, i.e., sink conditions

$$\frac{dC_b}{dt} = -\frac{A}{V}P_{app}C_b = -K_uC_b \tag{3}$$

where C_b is the total drug concentration in the lumen; $K_u = (\frac{A}{V})$; P_{app} , the apparent first-order absorption rate

Fig. 6 Schematic depiction of cellular uptake mechanisms: fluid-phase endocytosis, receptor-mediated endocytosis, and transcytosis. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

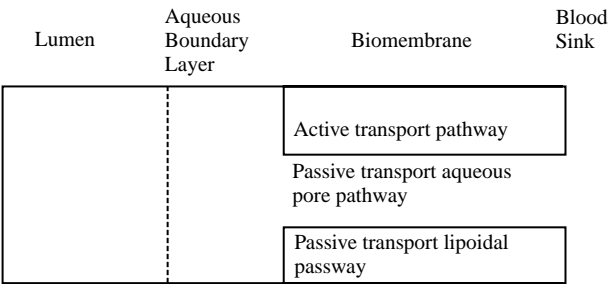

Fig. 7 The physical model for the simultaneous passive and active membrane transport of drugs in the intestinal lumen.

constant; A is the surface area; and V is the luminal solution volume.

Assuming no significant aqueous boundary layer on the blood side, the apparent permeability coefficient (P_{app}) in Eq. 1 is expressed by:

$$P_{app} = \frac{1}{\frac{1}{P_{aq}} + \frac{1}{P_{membrane}}} \quad (4)$$

With the use of Eq. 4, the absorption rate constant can be expressed as:

$$K_u = \frac{A}{V} \cdot \frac{1}{\frac{1}{P_{aq}} + \frac{1}{P_{membrane}}} \quad (5)$$

For highly lipophilic drugs ($\sim \log PC > 3.0$), the absorption rate constant will be dependent on the diffusion rate across the aqueous boundary layer in front of the membrane, and is expressed by:

$$K_u = \left(\frac{A}{V}\right) \cdot P_{aq} \quad (6)$$

and is also shown in illustration:

For the hydrophilic drugs such as peptides and proteins, the absorption rate constant will be dependent on the diffusion across the membrane ($P_{aq} \gg P_{membrane}$).

$$K_u = \left(\frac{A}{V}\right) \cdot P_{membrane} \quad (7)$$

Table 1 includes additional mathematical definitions of effective membrane permeability coefficient for various transport mechanisms.

During the past 10 years, it has been reported that the 170-kDa P-glycoprotein, which is known as the principal component of pleiotropic (multidrug) resistance (MDR) in tumor cells, works as an apically polarized efflux transporter (also known as an efflux pump). This efflux transporter opposes the transcellular movement of drugs in the epithelial cells. P-glycoprotein is known to be present in the apical region of epithelial cells in the kidney, liver, and GI tract. Many drugs are known to be substrates for this efflux transporter including cyclosporin A (16) and other peptides (17). The existence of efflux pumps for peptides is demonstrated by measuring the apparent permeability coefficient (P_{app}) values of peptides (e.g., cyclosporin A) using the Caco-2 cell culture model with and without efflux pump inhibitors. With efflux pump inhibitors (chlorpromazine and progesterone), the P_{app} value of apical to basolateral transport for both cyclosporin A increases significantly compared with the control (without inhibitors). In contrast, the basolateral to apical transport is decreased with an inhibitor. Cyclosporin A is a substrate for the efflux transporter P-glycoprotein, and the efflux pump is located on the apical side of the intestinal epithelial cells. Whenever unexplainable poor absorption of peptides is seen, the role of these efflux pumps should be examined.

Table 1 Effective membrane permeability coefficients for various transport mechanisms

Mechanism	$P_{membrane} =$
Passive diffusion of small electrolytes	$P_L X_s + P_p$
Passive diffusion of small nonelectrolytes	$P_L + P_p$
Passive diffusion of large nonelectrolytes	P_L
Passive transport of ampholytes	$P_L^{\pm} X_s^{\pm} + P_p^+ X_s^+ + P_p^- X_s^-$
Passive diffusion coupled with active transport	$P_L X_s + P_L^* (1 - X_s)$ where $P_L^* = J_{max}^* / K_L^*$

P_L is the permeability coefficient of the lipoidal membrane; P_p is the permeability coefficient of the aqueous pore; X_s is the fraction of unionized species; P_L^{\pm} is the permeability coefficient of the lipoidal membrane of neutrally charged species; P_p^+ , P_p^- is the permeability coefficient of aqueous pore of positively and negatively charged species, respectively; X_s^{\pm} , X_s^+ , X_s^- is the fraction of neutrally, positively, and negatively charged species at the membrane surface, respectively; P_L^* is the permeability coefficient of the membrane for active transport; J_{max}^* is the maximum flux for active transport; K_L^* is the Michaelis constant for active transport.

Paracellular transport

The primary barrier to paracellular transport is the tight junction (also known as *zonula occludens*), which plays a central role in sealing the intercellular space in epithelial cells (18). These tight junctions are located just under the brush border and form a seal between adjacent epithelial cells. Tight junctions act as a gate and fence to control the intercellular movement of molecules. In addition, tight junctions prevent free diffusion and intermixing of certain apical and basolateral plasma membrane proteins, resulting in polarization of the epithelial cell layers. These junctions are composed of paired intramembrane strands, which consist of lipid molecules and several protein components such as occludin, claudin-1, and claudin-2. Based on coexpression studies, it appears that claudin-1 and claudin-2 are more likely involved in sealing the tight junctions, and occludin plays a supporting role for coordinating and modulating functions of tight junctions (19). The strands are thought to contain multiple and discrete aqueous pores (12). The tight junctions are lined with fixed negative charges such as COO^- , SO_4^{2-} , and PO_4^{3-} ions present on the surface of glycoproteins and proteoglycans on neighboring cell membranes (20). Because the tight junctions are negatively charged, this barrier has cation selectivity. In general, cations diffuse through the tight junctions faster than anions (21). The radius of the tight junctions of the intestinal mucosa can be a critical factor for the paracellular transport of peptide and protein drugs. The radius of the tight junction is about 12 Å (22). Because of the size limit of the tight junction, only small molecules and ions are capable of diffusing through the paracellular route. Amino acids, dipeptides, and tripeptides may be small enough to be absorbed across the intestinal wall through the paracellular route, but polypeptides and proteins are restricted because of their size.

One approach for overcoming this diffusion restriction is to change the aqueous pore radius of tight junctions by coadministering drugs with enhancers. Numerous enhancers have been investigated to increase the permeability of the intestinal membrane. They can be categorized into two groups: anionic surfactants such as long-chain acylcarnitines, bile acids, disodium dodecyl sulfate, and sodium caprate, and calcium-chelating agents such as EDTA and citrate (17). The calcium-chelating agents reduce the levels of calcium and induce opening of tight junctions. The anionic surfactants open up the tight junctions by interacting with the cell membrane. It is very important to weigh the benefits versus the toxic risks of enhancers with respect to causing long-term, irreversible damage to the membrane. Very little work has been reported on the toxicological effects of enhancers. It is generally known

Fig. 8 Schematic representation of Caco-2 cell. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

that nonionic surfactants exhibit lower levels of toxicity than do ionic surfactants; however, the ionic surfactants are considered much more potent enhancers.

TECHNIQUES FOR ASSESSING THE INTESTINAL MEMBRANE PERMEABILITY

Various techniques have been used for assessing the permeability of drug molecules across the intestinal membrane including as everted sacs (23), brush border membrane vesicles (24), intestinal rings (24), recirculation method (25), modified in situ Doluisio technique (4), through-and-through in situ method (26), Caco-2 cell culture model (17), and human intubation method (27). During the last 10 years, the Caco-2 cell culture model (Fig. 8) has gained the most attention in the pharmaceutical industry. This human colon carcinoma cell line model has been shown to mimic the intestinal epithelial cells and is used for assessing the permeability of molecule (17). This Caco-2 cell model has been used as a routine screening tool for compounds produced by combinatorial chemistry.

In the Caco-2 cell experiment, the apparent permeability coefficient (P_{app}) is determined by the following equation:

$$P_{app} = \frac{1}{AC_{d,0}} \cdot \frac{dM}{dt} \quad (8)$$

where $C_{d,0}$ is the initial concentration of drug in the donor side, and M is the mass of the drug in the receiver side at the time t .

The apparent permeability coefficient is further defined in Eq. 9:

$$\frac{1}{P_{\text{app}}} = \frac{1}{P_{\text{aq}}} + \frac{1}{P_{\text{mono}}} + \frac{1}{P_{\text{F}}} \quad (9)$$

where P_{F} is the permeability coefficient of the filter support and P_{mono} is the permeability coefficient of the Caco-2 cell monolayer.

INTESTINAL ABSORPTION OF AMINO ACIDS, PEPTIDES, AND PROTEINS

Much is known regarding the uptake of food-derived amino acids and peptides from the GI tract. This is useful information to review because it gives insight into how peptide and protein drugs are likely to be absorbed.

Absorption of Amino Acids

The uptake of single amino acids is more active in the ileum than in the jejunum. The intestinal cell membrane contains many different amino acid transporters. Amino acids are absorbed across the brush border plasma membrane into the epithelial cell by certain specific amino acid transporters. Transporter types B, B^{0,+}, IMINO, β, and X_{AG}⁻ are sodium-dependent, and types b^{0,+} and y⁺ are sodium-independent transporters (1). The sodium-dependent transporters bind amino acids only after binding sodium. The amino acid-bonded transporter then undergoes a conformational change that dumps sodium and the amino acid inside the cell, followed by its reorientation back to the original form. The basolateral membrane of the absorptive cell contains additional transporters that carry amino acids from the cell into the blood. The amino acid transporters of the basolateral membrane are categorized as sodium-dependent types A and ASC and sodium-independent types asc, L, and y⁺ (1).

Transporter type X_{AG}⁻ is for the transport of acidic amino acids, and basic amino acids are preferred substrates for transporter type y⁺. The transporter types A and IMINO help the transport of amino acids such as proline and hydroxy-proline. The remaining transporters (B, B^{0,+}, β, b^{0,+}, ASC, asc, L) are for the transport of neutral amino acids. The intestinal absorption of amino acids is a stereochemically specific mechanism. The rate of absorption of the L-isomer is greater than that of the corresponding D-isomer when racemic mixtures of the amino acid are introduced in the small intestine (28).

Absorption of Small Peptides

After the break down of proteins by proteolytic enzymes, the pancreas, and brush border peptidases, the di- and tripeptides are absorbed through the epithelial cell membrane. Many studies have shown that intact di- and tripeptides are absorbed across the epithelial cell membrane by active transport via specific carrier systems. The absorption process is mediated by the hydrogen-coupled peptide transporter (PEPT1) located in the intestinal apical cell membrane (29). Because there are 20 amino acids, there may be 400 dipeptides and 8000 tripeptides with different molecular sizes and charges. This means that a single membrane transport system has a high affinity for di- and tripeptides but very low affinities for tetra- or higher oligopeptides. Peptide-like drugs such as angiotensin-converting enzyme (ACE) inhibitors, bestatin, cephalosporins, beta-lactam antibiotics, and renin inhibitors are recognized by peptide transporter because of their structural similarities with small peptides. Once inside the enterocyte, the vast majority of di- and tripeptides are digested into amino acids by intracellular peptidases and are exported from the cell into the blood. Only a very small number of these small peptides enter the blood intact. Peptides that are resistant to hydrolysis by cytoplasmic peptidases exit across the basolateral cell membrane by less well-studied basolateral peptide transporters. The sodium/hydrogen exchanger maintains the incoming proton gradient on the apical membrane side, whereas the sodium/potassium-ATPase in the basolateral

Fig. 9 Model of peptide transport across intestinal epithelial cells. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

Table 2 GI Absorption of peptides and peptidelike drugs

Compound	MW ^a	Extent of absorption (%)	Reference
Dietary di- and tripeptides	200–300	5–50	(30)
Aminocephalosporins	350	>50	(31)
Enalapril	377	>50	(32)
Dietary tetrapeptides	≈400	≈5	(28)
Thyrotropin-releasing hormone (TRH) analogs	≈400	≈5	(28)

Leuprolide	1208	<5	(36)

^a Molecular weight.

membrane maintains a low intracellular sodium concentration. Thus, the sodium/hydrogen exchanger coupled with the sodium/potassium-ATPase drives the transport of di- and tripeptides across the epithelial cells (Fig. 9). The intestinal peptide transporter PEPT1 can transport di- and tripeptides but not free amino acids or tetrapeptides.

The intestinal absorption of dipeptides is a stereochemically specific mechanism. Dipeptides of L-L forms are transported more easily than are their isomers with a D-Amino acid. Dipeptide isomers of the L-L form have the highest absorption rates, followed by L-D and D-L isomers, and then D-D isomers.

The intestinal absorption mechanisms of amino acids and di- and tripeptides are characterized relatively well, as described above. However, only a limited amount of

work has been published for the absorption of tetra- and higher peptides, and the results are somewhat mixed. In general, it appears that tetra- or higher peptides are not well absorbed from the GI tract. Table 2 shows the oral bioavailability of peptides and peptide-like drugs (molecular weight <1500).

Absorption of Polypeptides and Proteins

Enterocytes of the intestinal membrane do not have transporters to carry polypeptides and proteins across the intestinal membrane, and they certainly cannot permeate through tight junctions because of their size. Also, polypeptides and proteins are substrates for luminal, brush border, and cytosolic enzymes. Therefore, as

Table 3 GI Absorption of polypeptide and protein drugs

Compound	MW ^a	Extent of absorption (%)	Reference

illustrated in Table 3, peptide/protein drugs are poorly absorbed across the GI tract.

One exception to the poor absorption of intact proteins is that neonates have the ability to absorb intact proteins for a few days after birth. Absorption cells of the neonatal mammalian intestine are functionally and morphologically specialized for the uptake and transport of milk macromolecules (39). The newborn has low levels of proteolytic enzymes in the intestinal lumen, and this highly unique endocytic mechanism allows intact proteins to adhere to the epithelial cell membrane and transport across the cell membrane. This function is very important for newborns to acquire passive immunity by absorbing immunoglobulins in colostral milk. In contrast to humans and rodents, many animals such as cattle, sheep, horses, and pigs do not provide enough antibodies across the placenta, and the young are born without circulating antibodies. Therefore, for these animals, the acquisition of passive immunity after birth depends primarily or entirely on the uptake of immunoglobulins in the small intestine by the endocytic mechanism. In addition, the highly endocytic nature of the small intestine provides no protection to invasion of bacterial proteins and antigens. At maturation, there is an abrupt change in the epithelial morphology of the small intestine that results in the cessation of the highly endocytic nature of the epithelium and in the corresponding loss in the capacity to absorb intact proteins.

Although the adult intestine provides a more effective epithelial barrier than that in newborns, evidence indicates that small quantities of intact proteins are transported across intestinal epithelial cells. There are two possible mechanisms associated with the absorption of intact proteins: endocytosis and transport through the epithelium of Peyer's patches.

Endocytosis

The epithelial membrane of the GI tract consists of a continuous barrier of cells, which allows the transport of low-molecular-weight molecules by simple diffusion or various carrier processes. Macromolecules such as proteins may be absorbed from the intestinal lumen by cellular vesicular processes, through fluid-phase endocytosis (pinocytosis), or by receptor-mediated endocytosis or transcytosis (Fig. 6). In pinocytosis, extracellular fluid is captured within an epithelial membrane vesicle. It begins with the formation of a pocket when a localized region of the epithelial membrane sinks inwardly. As the pocket deepens, it pinches into the cytoplasm, forming a vesicle containing the macromolecule that had been outside the cell. As a consequence, the majority of macromolecules taken into the cell by the vesicle do not find their way into the underlying tissues and thence to the blood circulation.

Rather, the vesicle shuttles the macromolecule to an endosome, which fuses with a lysosome where the membrane is recycled back to the epithelial membrane and the macromolecule is degraded. For example, HRP is taken up by the cell through the endocytosis process in the rabbit jejunum, and approximately 97% of these molecules are degraded during passage through the lysosomal system (37). Pinocytosis is unspecific in the substances it transports. Certain viruses and micro-organisms get into the cells by the endocytic mechanism, but they are not broken down within the lysosomal system. Some parasites and micro-organisms actually live within the lysosomal system, whereas others can find their way into the cytoplasm through mechanisms that may involve the presence of certain structures on membrane surfaces or changes in lysosomal pH.

In contrast, receptor-mediated endocytosis is very specific. Embedded in the membrane are proteins with specific receptor sites exposed to the extracellular fluid. The receptor proteins are usually clustered in regions of the membrane called coated pits, which are lined on their cytoplasmic side by a fuzzy layer consisting of a protein called clathrin. When ligands bind to the receptor sites, they are carried into the cell by the inward budding of a coated pit to form a coated vesicle. Clathrin-coated vesicles become uncoated and fuse to form an endosome. Ligand and receptor dissociate within the endosome, and the receptor shuttles back to the cell surface. The endosome fuses with the lysosome on which ligand degradation occurs.

Transcytosis is a process by which an endocytic vesicle (endosome) carries its contents across the epithelial cell without fusion with a lysosome (Fig. 6). The majority of endocytosed proteins are degraded, indicating that the transcytotic pathway is a minor one, with most endocytosed protein being routed to lysosomes. According to careful measurement (37), only 3% of horseradish peroxidase (HRP) avoids fusion with the lysosomal compartments to reach the blood circulation. However, it is interesting to note that immunoglobulin A (molecular weight ≈ 160 kDa) and immunoglobulin M (molecular weight ≈ 970 kDa) internalize into the cell by receptor-mediated endocytosis and are conveyed from one side of the cell to the other without fusing with the lysosome. It would be very interesting to explore whether the transcytosis process of immunoglobulins and the above-mentioned endocytosis processes of microorganisms and parasites, in which no degradation by the lysosomes occurs, could be harnessed for the delivery of peptides and proteins.

Transport through the epithelium of Peyer's patches

Although the GI tract has effective barrier properties, the mucous membrane is one of the major sites of entry for

most pathogens. The defense of these vulnerable membrane surfaces is provided by organized structures of lymphoid follicles known as Peyer's patches. Peyer's patches were discovered by Johanni Peyeri in 1677 and consist of 30 to 40 lymphoid nodules on the outer wall of the intestines (40). They are most prominent in the ileum of the small intestine in humans and are characterized by the presence of specialized epithelial cells called M (microfold or membranous) cells. Morphologically, M cells are quite different from absorptive cells. Their apical luminal surface contains numerous microfolds, truncated microvilli, and low levels of membrane-bound enzymes. In addition, M cells possess a relatively sparse glycocalyx and almost no lysosomes. Furthermore, the basolateral membrane surfaces of M cells are deeply invaginated toward the luminal side to form a pocket that is filled with a cluster of B cells, T cells, and macrophages (Fig. 10). All these unique structural characteristics of M cells are specialized for endocytosis of macromolecules or particles and transport to the lymphatic system. Several proteins such as native ferritin, HRP, and lectins are taken up by a pinocytosis process and traverse across M cells from the lumen to the extracellular space. This is in contrast to immunoglobulin A, which is internalized by a receptor-mediated endocytosis process, as described in the previous section. In addition to macromolecules, viruses and bacteria have been shown to gain entry via the Peyer's patches. The HRP concentration affects the transport process from the lumen to the lymph system; low levels of HRP are predominantly taken up by M cells, but higher levels are simultaneously taken up by M cells as well as by

absorptive cells (39). HRP is transported through the intestinal segments containing Peyer's patches more quickly in the intact form than through neighboring patch-free segments. The apparent permeability coefficient (P_{app}) of HRP in the segment containing Peyer's patches is approximately seven-fold larger than in the segment without Peyer's patches (41).

APPROACHES TO IMPROVE THE ORAL ABSORPTION OF PEPTIDES AND PROTEINS

As noted in the introduction to this article, the oral absorption of peptides (>3 amino acids) and proteins is very poor because of their potential degradation by the strong acidic environment and enzymes in the GI tract. Also, peptides and proteins have a very low permeability across the GI membrane.

Various formulation concepts have been introduced as potential ways to protect peptide and protein drugs from the hostile GI environment to increase their oral absorption such as use particulate drug carriers (microspheres, lipo-somes, and lectins), coadministration of enzyme inhibitors and absorption enhancers, use of chemical modification (prodrug), and site-specific delivery to the colon or rectum. Some of these approaches are discussed later.

Proteinoid Microspheres

Protenoids are thermally condensed amino acids and spontaneously form microspheres when exposed to an acidic medium (42). The microsphere size is approximately 1–5 μm in diameter. The proteinoid microspheres are very stable at lower pH conditions of 1 to 3 but unstable at the pH range of 6 to 7. Therefore, the proteinoid microspheres are able to protect the peptide and protein drugs from the gastric acids and enzymes while in the stomach and to release the encapsulated drug in the small intestine to be available for absorption. The proteinoids are also able to inhibit the activity of peptidases such as trypsin and chymotrypsin. Oral administration of proteinoid encapsulated insulin in diabetic rats has shown a significant hypoglycemic effect and provided a longer duration of action than when administered subcutaneously. Also, proteinoid-encapsulated calcitonin has been shown to significantly decrease serum calcium levels in treated rats compared with rats in a placebo control group. Both results demonstrate that proteinoid encapsulation can enhance the oral absorption of peptide and protein drugs (42).

Fig. 11 Types of liposome: unilamellar liposome and multilamellar liposome. (Illustration by Leigh A. Rondano, Boehringer Ingelheim Pharmaceuticals, Inc.)

Liposomes

Liposomes have received considerable attention as a possible delivery tool for peptide and protein drugs by protecting labile compounds from degradation or by enhancing the uptake of poorly absorbed compounds. Liposomes have been studied extensively as a potential oral delivery system for proteins, especially insulin, and the oral administration of liposome-entrapped insulin into diabetic rats has produced a significant fall in blood glucose levels (43). There are three types of liposomes: multilamellar liposomes (MLV), 0.05–10 μm small unilamellar liposomes (SUV), 0.025–0.05 μm and large unilamellar liposomes (LUV), 0.2–2 μm (Fig. 11).

Liposomes are defined as vesicular lipid bilayers that enclose a volume of aqueous solution. Liposomes can be formed from a variety of phospholipids. The most widely used lipid is phosphatidylcholine. The liposome's outer membrane is semipermeable, and its permeability can be altered by varying the types of lipids used in preparing the liposomes. Liposomes can be made with a high permeability by using unsaturated lipids that will make a more fluid membrane. However, liposome with low permeability can be obtained by using a mix of phospholipids and cholesterol. Cholesterol is known to condense the packing of the phospholipids, thereby reducing their permeability and increasing the stability of the phospholipid bilayers. Negatively charged liposomes can be prepared by using phosphatidylserine or phosphatidylglycerol, and positively charged liposomes are made using stearylamine. Three possible mechanisms in the membrane transport of liposome-entrapped drugs

have been proposed (44): free molecule mechanism, simultaneous free molecule and direct liposome/membrane mechanism, and direct liposome/membrane mechanism. The free molecule model is for water-soluble drugs and includes the diffusion of a drug molecule from the liposome into the lumen first and then by membrane transport of the free molecule. The simultaneous free molecule and direct liposome/membrane mechanism is the sum of the permeations attributed to the drug molecule in the lumen and the direct transfer of molecule between liposome and membrane. The last mechanism, the direct liposome/membrane mechanism, is for water-insoluble drugs. This mechanism likely occurs because the release kinetics from a liposome system into the lumen is negligible.

Since 1970, there have been numerous reports detailing the advantages of liposomes as drug-delivery systems. However, in general these systems have not been successful for oral delivery. Some of the reasons may be related to: 1) their lack of stability in the GI tract and 2) their susceptibility to changes in pH, bile salts, and lipases. In addition, it has been shown that liposome systems are immunogenic.

Lectins

Lectins are known to have specific binding properties to the epithelial cell surface and have been tested as a possible oral delivery system for peptide and protein drugs. The lectin-coated nanoparticles that contain peptide or protein drugs can protect against degradation in the lumen of the small intestine and facilitate the uptake of

peptide or protein drugs across M cells by acting as a specific targeting ligand.

Coadministration of Enzyme Inhibitors

To promote the oral absorption of polypeptide and protein drugs from the GI tract, the enzyme barrier must be overcome. Various protease/peptidase inhibitors have been tested to enhance the oral bioavailability of peptide and protein drugs. To date, the known inhibitors are aprotinin, bacitracin, Bowman–Birk inhibitor, camostat mesilate, soybean trypsin inhibitor, sodium glycocholate, and chymotrypsin inhibitor (FK-448). Some of these inhibitors have absorption-enhancing activity in addition to enzymatic inhibition activity. As an example, insulin has often been used as a model protein drug in studies on enzymatic inhibition activity. Trypsin inhibitor and aprotinin have shown a marginal effect on increasing insulin absorption in rats. However, a significant hypoglycemic effect has been observed after administration of insulin with sodium glycocholate, camostat mesilate, and bacitracin (45), which may be related to the fact that these compounds act not only as enzymatic inhibitors but also as absorption enhancers. Although various potential candidates for enzyme inhibition and absorption enhancers have been identified, the long-term safety of these compounds in humans must be evaluated further.

Coadministration of Absorption Enhancers

Most polypeptide and protein drugs show low permeability across the intestinal membrane because of their polarity and size. Therefore, one approach to increase the permeability of these drugs is to coadminister with absorption enhancers. Thus far, the known enhancers tested for the oral delivery of peptide and protein drugs are bile salts, nonionic surfactants, anionic surfactants, lysolecithin, amines, medium chain glycerides, and salicylates. Although their mechanisms of action are not well understood, several possible mechanisms have been proposed, especially for insulin absorption, which include: 1) that some enhancers, such as bile salts, act not only as an absorption enhancer but also as an enzyme inhibitor; 2) that the enhancers act as a kind of dispersing agent to prevent aggregation of peptide and protein molecules in solution, resulting in increased solubility of the drugs; 3) that the enhancers reduce the viscosity of the membrane mucous layer and increase the membrane fluidity, resulting in increased absorption by opening up the aqueous channel on the cell membrane; and 4) that the positively charged enhancers may interact with the negatively charged epithelial cell membrane and neutralize the membrane

surface, resulting in increased absorption of the protein. Most enhancers are known to cause membrane irritation, and their long-term toxicity has not been well characterized and must be established (46).

Chemical Modifications

The reasons for poor absorption of most natural peptides and proteins from the GI tract are that most natural peptides and proteins are hydrophilic compounds and have a low partition coefficient (log of octanol/water partition coefficient, log P) on the order of -1 . For example, the log P values of TRH and vasopressin are -1.43 and -2.15 , respectively. There are some exceptions such as cyclosporine. Cyclosporine is a lipophilic peptide (log P = 3.0) and exposes very few polar groups on the surface. Medicinal chemists have routinely applied three types of chemical modification to improve the absorption of peptide and protein drugs including analogs, irreversible derivatives, and prodrugs. The irreversible derivative and the analog approaches are usually applied when compounds exhibit poor absorption because of in vivo metabolism. Peptide drug examples include enkephalins, TRH, and vasopressin, and insulin can be a model for protein drugs. The chemical modifications by the irreversible derivative and the analog approaches can prevent hydrolysis of peptides or proteins; however, these modifications may also reduce biological activity. For example, chymotrypsin, one of the major peptidases secreted by the pancreas into the intestinal lumen, is known to cleave at five bonds within the insulin molecule in a very short time. Four of these five residues play an important role in maintaining the biological activity of insulin and are essential for receptor binding ability (47). A number of chemical modifications at these sites could produce greater chemical stability; however, such changes in the insulin molecule could result in a loss in activity because of possible alterations of the three-dimensional structure of the protein.

The prodrug approach is the most widely applied chemical modification for improving the absorption of peptides. The unique feature of the prodrug approach is that the optimum physicochemical properties required for the drug with respect to lipophilicity and degradation can be achieved without altering the intrinsic biological activity of the parent drug. The prodrug itself is inactive. However, once the peptide prodrug is absorbed, it is converted to an active peptide, usually by an enzyme. A good example is an ACE inhibitor, enalapril, which was found to be orally well absorbed and metabolized to the active form, enalaprilat, in the liver. In contrast, the parent drug, enalaprilat, is very poorly absorbed via the oral route.

Colon Delivery

The colon has received considerable attention as a possible delivery site for peptide and protein drugs because enzymatic activities, especially peptidases, are significantly lower in the colon compared with the small intestine, and the residence time in the colon is longer than in the small intestine. However, there are some drawbacks for site-specific delivery of peptide and protein drugs in the colon as follows:

1. The colonic mucosa does not have the villi and microvilli of the small intestine. Therefore, the surface area available for absorption in the colon is considerably less than that in the small intestine.
2. Peptidases such as aminopeptidases and diaminopeptidases are at lower concentrations in the colon than in the small intestine. However, it has been shown that prolyl endoprotease and collagenase activities are five to six times higher in the colon than in the small intestine. TRH is more readily hydrolyzed to deaminated TRH in colonic homogenates compared with small intestine and rectum. Therefore, peptide drugs that are substrates for prolyl endoprotease and collagenase will likely be degraded in the colon and may not be suitable for colon delivery.
3. The concentration of bacteria in the colon, largely anaerobic species, is much higher than that in the small intestine. This high concentration of bacteria may lead to faster degradation of certain drugs such as digoxin, which is degraded to dihydrodigoxin by the microflora in the colon.

The microflora degradation mechanism has been exploited as a possible tool for the site-specific delivery of peptide and protein drugs. Peptide and protein drugs are coated with azoaromatic groups to form an impermeable film to protect them from digestion in the stomach and small intestine. When the polymer-coated peptide and protein drugs reach the colon, the colonic bacteria cleaves the azo bonds and breaks the polymer film, releasing the drugs into the lumen of the colon for absorption. This polymeric system was demonstrated to protect and deliver orally administered insulin and vasopressin (7) in rats.

Rectum Delivery

In general, oral delivery of polypeptide and protein drugs is limited because of degradation in the GI tract and poor absorption through the membrane. Rectal administration offers some advantages compared with oral delivery, such as low enzymatic activity, neutral pH, and partial avoidance

of first-pass metabolism. Even though the rectal route has long been known as a specific absorption site for the delivery of small lipophilic molecules, rectal delivery of large hydrophilic molecules is problematic because of poor absorption, and absorption enhancers may be required. Increased absorption of peptides, such as des-enkephalin-gamma-endorphin and desglycinamide arginine vasopressin, and proteins, e.g., albumin, insulin, and a somastatin analog, has been demonstrated by coadministration with enhancers. The enhancers used for the rectal absorption of insulin are surface active agents; bile acids; EDTA; and phospholipids such as lecithin, saponins, sodium salicylate, organic alcohols, acids, amines, and fats. Their mechanisms of action are generally not fully understood. Some of the possible enhancing mechanisms are described in "Coadministration of Enzyme Inhibitors," previously.

CONCLUSION

Rapid developments in biotechnology have led to the production of large quantities of pure potent and highly specific polypeptide and protein drugs. To date, they have been administered primarily by the parenteral route, even though the oral route is the patient's preferred choice. The oral route offers many advantages over parenteral administration, such as ease of administration and increased patient compliance. However, in general the peptide and protein drugs are very difficult to administer orally because they are of large molecular weight, hydrophilic in nature, and substrates for peptidases and proteases in the GI tract. There are many different locations where peptide and protein drugs can be hydrolyzed after oral administration. Their exposure to the strong hostile acidic environment of the stomach may cause partial degradation. Further degradation occurs in the lumen of the small intestine by the peptidases secreted by the pancreas, and then additional degradation by enzymes on the brush border and inside the epithelial cells follows. Even if some of the peptide and protein drugs survive and enter the cell, as they diffuse across the cell, they are taken up by lysosome where most of them are hydrolyzed by the lysosomal enzymes. Finally, those peptide and protein drugs that get through the epithelial cell into the portal vein could still be metabolized by the liver. In addition, they usually show poor permeability across the intestinal membrane because of their molecular size and polar nature.

To minimize degradation and improve absorption of peptide and protein drugs administered orally, several factors are significant. First, peptide and protein drugs

have to be protected from the acidic environment in the stomach and from enzyme degradation in the lumen and on the brush border of the small intestine. This may be accomplished by coadministration of peptidase inhibitors or by chemical modifications, such as analogs or prodrug approaches, or formulation approaches, such as microspheres and liposomes.

Second, because of their molecular size and hydrophilic nature, peptide and protein drugs are poorly absorbed through the intestinal membrane, and absorption has to be improved. This may be accomplished by coadministration of penetration enhancers or by chemical modifications such as increasing lipophilicity.

Finally, all these approaches may be possible; however, there is still a major hurdle to overcome: how intact peptide and protein drugs may pass across the inside of the epithelial cell without being taken up by the lysosome and also bypass first-pass metabolism in the liver. The best chance of avoiding lysosomal uptake and first-pass metabolism is by diffusion through the M cells on the Peyer's patches, which contain almost no lysosomes, and unloading the diffusates directly into the lymphatic system. This may be accomplished by exploring whether the transcytosis mechanism of antigens or microparticulates across the intestinal wall could be applied for the delivery of peptide and protein drugs.

In conclusion, although oral delivery is the preferred route for peptide and protein drugs, there are many drawbacks, as addressed previously. Successful oral delivery of peptide and protein drugs is likely to remain a formidable challenge for some time.

PEPTIDES AND PROTEINS—PULMONARY ABSORPTION

Igor Gonda

Aradigm Corporation, Hayward, California, U.S.A.

INTRODUCTION

The human respiratory tract has the potential to provide the means for noninvasive drug delivery of molecules that could not be efficiently and reproducibly, or rapidly, delivered without injecting them into the body. From the early parts of the 20th century, there have been many attempts to use inhalation to deliver insulin for the treatment of diabetes (1). These early approaches failed because the aerosol generators (jet nebulizers and metered dose inhalers) had low and variable delivery to the lung. Inhalation therapy for the treatment of diseases of the respiratory tract, especially asthma, underwent spectacular growth in the last three decades of the 20th century (2). The discovery of potent drugs that could be administered in one or two puffs from a low cost hand-held device, such as a metered dose inhaler or dry powder inhaler, led to the acceptance of aerosols as the preferred mode of therapy of asthma. One of the main advantages of targeting the lung was the minimization of systemic side effects of these drugs. Nevertheless, it was observed already in the early development of these asthma products that systemic absorption of the inhaled drugs did occur (3).

The biotechnology revolution resulted in the production of many potentially valuable therapeutic proteins. However, it was recognized that these molecules had properties that necessitated the use of injections for their administration. Intensive research in noninvasive drug delivery accompanied the dawn of recombinant biologics, but it met with somewhat limited success. Early work on peptides such as insulin (1) and some proteins (4) certainly indicated that such molecules were absorbed from the lung. Mackay et al. (5) reported in 1994 a summary of extensive studies in which the absolute bioavailabilities of several proteins and peptides were measured in rat models of pulmonary, nasal, and colonic absorption. The compounds were human and salmon calcitonins, the human parathyroid hormone and its 34-peptide fragment, hirudin, and a hybrid alpha interferon. All routes of administration exhibited general reduction of bioavailability with increasing molecular

weight. However, the pulmonary route (via intratracheal administration) resulted in much higher values than the other two routes. Thus, pulmonary delivery was known to be exceptionally promising among the noninvasive routes of delivery of peptides and proteins, but the key reasons for its poor delivery efficiency and variability needed to be investigated and removed. Industrial and academic research in the latter part of the last century demonstrated the need for targeting of the drug into “deep lung” to increase the efficiency of delivery and in particular to avoid the highly variable deposition in the oropharyngeal cavity (6). The conventional therapeutic aerosol generators used for delivery of asthma drugs to the airways were not designed with these requirements in mind. New types of delivery systems had to be developed that could generate very fine particles with aerodynamic properties suitable for drug delivery to the distal part of the respiratory tract with large highly absorptive surfaces.

SAFETY OF PROTEINS AND PEPTIDES DELIVERED TO THE LUNG

Satisfactory efficiency of delivery is only meaningful when it goes hand-in-hand with adequate safety. The inhalation route in general has been associated with a very good safety record for the delivery of asthma drugs evidenced both during the development stages and by their wide acceptance postapproval. The experience with inhaled protein and peptide drugs is so far relatively limited. Overall, the pulmonary safety of inhaled proteins and peptides has been good (7). The most extensive preclinical and clinical experience thus far is available for the recombinant human deoxyribonuclease (rhDNase) approved by inhalation for the treatment of cystic fibrosis in 1993 (8, 9). Inhaled leuprolide, a small peptide, was extensively studied with “clean” preclinical and clinical safety findings (10). A new large safety data base is being generated in conjunction with late stage development of insulin by several companies (11, 12).

ABSORPTION AND OTHER CLEARANCE MECHANISMS IN THE RESPIRATORY TRACT

Absorption of the protein and peptide molecules delivered to the respiratory tract competes against various other clearance mechanisms. When a particle containing a therapeutic substance is deposited in the respiratory tract, the following mechanisms of the drug-containing particle clearance can take place:

Removal of particulates from the respiratory tract:

- Mucociliary clearance
- Phagocytosis
- Clearance of the phagocytosed particles

After the drug is released from the particle (e.g., by dissolution, diffusion, or erosion), the three above listed mechanisms can also clear the free drug. Additional clearance of the released drug can take place as follows:

Removal of molecules deposited in the respiratory tract:

- Metabolism
- Chemical (non-enzymatic) decomposition
- Binding to fluid and tissue components in the respiratory tract
- Lymphatic uptake
- Absorption into blood stream

Absorption, Phagocytosis, and Mucociliary Clearance

These clearance pathways are not distributed uniformly throughout the lung. The gas-exchange areas, for example, do not have the mucociliary clearance but they have alveolar macrophages that can phagocytose “foreign” materials. These alveolated regions also have a much greater and more permeable environment than the upper and conducting airways. The main barrier in the deep lung to transport into blood stream appears to be the alveolar epithelium rather than the endothelial cells. While the majority of the cells lining the alveoli are Type II, most of the surface area (~95%) is covered by Type I cells. Alveolar cell monolayers resembling Type I cells are therefore thought to be representative of the barrier for pulmonary absorption.

Several authors reported on the biphasic nature of peptide and protein absorption from the lung (13, 14). The rapid component was proposed to be representing paracellular absorption through water-filled pores. The origins of the slower absorption phase into the blood circulation are not well understood. The respiratory tract has a rich lymphatic system, and, in addition to transcellular

and paracellular transport into the blood circulation, it is possible that a significant portion of macromolecules ends up first in the lymphatic system and is only then slowly released into the blood circulation. The molecular weight dependence of transfer of materials into the intrapulmonary lymph nodes following intratracheal administration in the rat was investigated with a series of labeled dextrans. It was found that the threshold for increased ratio of blood/lymph transfer was between 10 and 20 kDa, similar to the large intestine. Certain absorption enhancers were found to increase this ratio, suggesting that the use of such materials could be exploited in the future to target therapeutics into the pulmonary lymph nodes (15).

The clearance mechanisms have been modeled quantitatively to get a better understanding of the effects of interplay of the complex kinetics on the magnitude and duration of residence in the lung (Fig. 1) (16). This model can be significantly simplified if only a few of the pathways dominate the transport and a only low-resolution compartmental analysis is experimentally feasible (17).

Colthorpe et al. (17) showed that the mucociliary clearance is the elimination pathway that contributes most to the reduction of bioavailability of insulin, at least in the rabbit model they studied. Thus, the less insulin is deposited on the conducting airways and the more that gets into the nonciliated gas exchange spaces, the higher is the bioavailability. Similar conclusions were reached studying the pulmonary absorption of growth hormone in the same model (18). The pulmonary to blood transfer rate constants were found to be also somewhat higher for the aerosol delivery compared with intratracheal administration. This is consistent with the pioneering work of Schanker's group (19), who showed in experiments with inhibited mucociliary clearance that the aerosol technique results in faster absorption rates presumably associated with the coverage of a bigger surface area of the respiratory tract and better penetration into the permeable lung periphery. This was confirmed more recently also in the work of Niven et al. (20) in which they compared instillation of liquid formulations, powder insufflation, and aerosol delivery of recombinant human granulocyte colony stimulating factor (rhG-CSF) and its pegylated derivatives in several species. They highlighted the fact that the nature of the distribution of the drug in the respiratory tract has a far greater impact on the rate and extent of absorption than even the molecular modifications. Similarly, it was shown (21) that the bioavailability of leuprolide administered to dogs increased with the downstream distance from epiglottis. In humans, Newman et al. (22) compared the bioavailability of a peptide molecule delivered to human volunteers in the form of inhaled “coarse” and “fine” aerosols. The ratio of

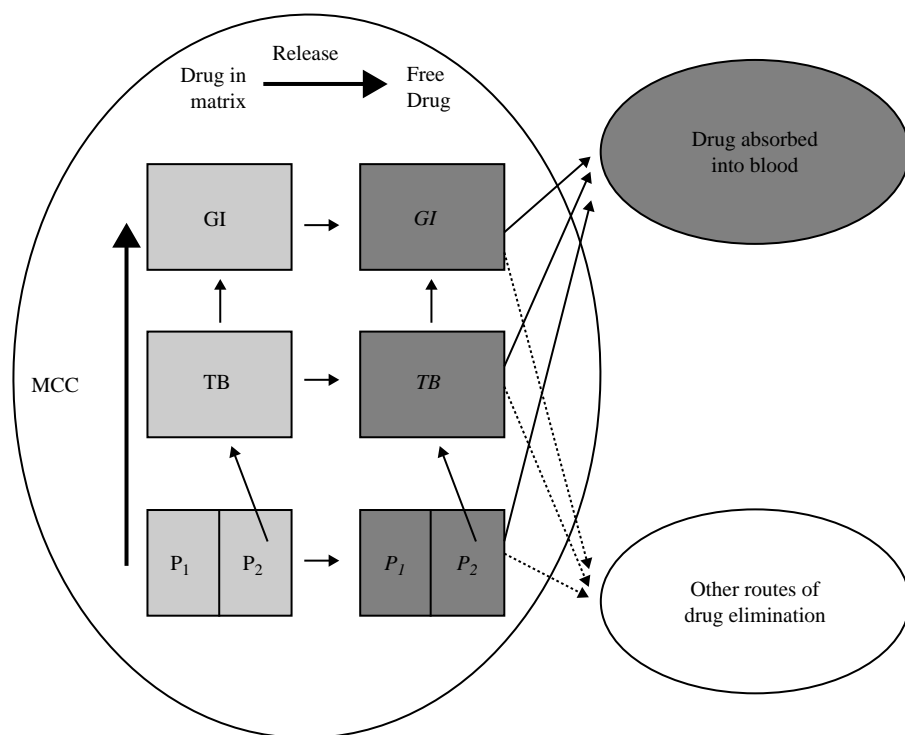

Fig. 1 Inhaled drug in a carrier can exist in the slow clearing pulmonary compartment (P_1) without mucociliary clearance or in the faster clearing pulmonary compartment with mucociliary clearance (P_2), tracheobronchial compartment (TB) or gastrointestinal tract (GI). When the drug is released into these compartment (the released drug is represented by italicized letters P_1 , P_2 , TB, GI), it can be absorbed into the bloodstream, or it can be removed by non-productive pathways such as mucociliary clearance represented by the vertical arrows, or chemical and enzymatic decomposition. Large molecules may also enter lymphatics before they appear in the blood stream. (The detailed model was described in Ref. 16 while the simplified three-compartment model represented by the ellipses is from Ref. 17.)

the bioavailabilities was almost identical to the ratio of the mass of the drug delivered to alveoli (as assessed by external gamma scintigraphic measurement). Getting protein deeper into the lung to access greater and more permeable surface areas that are not cleared by the mucociliary escalator thus results in better bioavailability.

Recent work with insulin provides evidence that the total lung volume at the end of the delivery impacts the kinetics of absorption of this peptide: delivery of fine particle insulin aerosol resulted in faster absorption with a higher plasma peak level in humans when the inhalation was done with a deep breath (close to vital capacity), as compared with a more shallow breath (about 50% of the vital capacity) (14, 23). The kinetics following the latter was similar to subcutaneous absorption of insulin. The exact reasons for this observation are unknown. However, the lung does have the above-described water channels that could expand during breathing. If the size of the peptide or protein molecule approaches the diameter of these channels, it would be expected that the channel expansion would lead to faster absorption. For molecules whose size

exceeds the channel diameter, the lung volume does not play a role in their pulmonary absorption rate (24).

Age, Disease, and Smoking Effects on Protein and Peptide Absorption

The effect of age on pulmonary absorption of three macromolecular markers, bovine IgG (BigG, MW = 150 kDa), bovine serum albumin (BSA, MW = 67 kDa), and 1-deamino-cysteine-8-D-arginine vasopressin (dDAVP, MW=1.067 kDa) was studied following intratracheal instillation in young and adult rats. The bioavailabilities for the three compounds were approximately 1.5, 5, and 20% in the adult rats. Low bioavailabilities were also found in the young rats for BigG and BSA but the absorption of dDAVP was significantly increased to 45% (25). Smoking profoundly increases the rate of absorption of insulin (26).

In experiments with aerosolized BSA and dDAVP in the rat (27), acute inflammation markedly increased the bioavailabilities.

Absorption Enhancers

The use of absorption enhancers for pulmonary delivery of peptides and proteins has been investigated in animal models but has not found commercial applications yet. This is presumably out of concern for potential safety impact from the use of such excipients. For example, Yamamoto et al. (28) showed that bacitracin and *N*-lauryl-beta-D-maltopyranoside in particular enhanced pulmonary absorption of insulin in a rat model but the toxicity of these enhancers was not investigated. The mechanism of “absorption enhancement” by bacitracin could have been in fact suppression of enzymatic degradation. Protease inhibitors were also found to improve the pulmonary absorption of a calcitonin analog (29) in a rat model but the mechanisms of this enhancement, or the potential pulmonary toxicity, were not studied. Changes to the barrier properties ranging from transient effects to complete stripping of epithelial cells have been among proposed mechanisms of pulmonary absorption enhancement.

Metabolism of Proteins and Peptides

There does not appear to be any significant proteolytic degradation by enzymes in the extracellular fluid in normal human airways and alveoli. However, the presence of peptidases makes absorption of small peptides variable and difficult to predict. Peptidase-resistant peptides generally show better bioavailabilities than other peptides with comparable molecular weights (30). Difference in metabolism and absorption of D and L forms of peptides glycyl-D-phenylalanine and glycyl-L-phenylalanine was demonstrated by Morimoto et al. (31). The L peptide was subject to metabolism, and it had significant paracellular transport with a smaller transcellular component. In contrast, the D peptide was not metabolized and it was only transported by passive diffusion via the paracellular route.

Given the complexity of the clearance mechanisms and the differences in the anatomy and physiology of the respiratory tract among various animal species, it is not surprising to find that the absorption rate constants for proteins and peptides are difficult to predict with any degree of accuracy. Fig. 2 shows the dependence of the apparent absorption rate constants as a function of molecular weight in dogs, rabbits, rats, and humans. While it is clear that generally the rate of pulmonary absorption is reduced for bigger molecules, the actual rate for a macromolecule in humans can be reliably determined at present only through direct experimentation.

Fig. 2 Apparent pulmonary absorption rate constants as a function of molecular weight calculated from data in Refs. 17, 18, 32–34. (From Dr. Glyn Taylor, University of Wales, Cardiff, UK, and Dr. Stephen Farr, Aradigm Corporation, Hayward, CA.)

REGIONAL DEPOSITION OF INHALED PARTICLES AND DROPLETS IN THE HUMAN RESPIRATORY TRACT

Since the human respiratory tract is anatomically and physiologically a very heterogeneous system, the rate and extent of absorption of macromolecules as well as their potential adverse reactions depend on the regional doses. The most convenient method to deliver drugs to the respiratory tract is by inhalation. Other methods of delivery such as intratracheal instillation are used in experimental settings but are generally unsuitable for real-life therapeutic products. This section describes the basics underlying the deposition dosimetry following inhalation of particles.

Aerodynamic Particle Size

The probability of deposition of particles in the various parts of the human respiratory tract depends on their aerodynamic diameter, D_{ae} . This parameter in turn is a function of the physical dimensions, shape, and density of the particles. For spherical particles, the aerodynamic diameter is simply

$$D_{ae} = D \times \sqrt{(\rho/\rho_0)}$$

where D is the physical diameter, ρ is the density of the particle, and ρ_0 is unit density (in the old cgs units, it was

1 g/cm³). For droplets containing dilute aqueous solutions, the aerodynamic diameter is therefore equal to the geometric diameter of the droplet. For porous particles, the ratio of densities can be less than one, in which case the geometric diameter is larger than the effective aerodynamic diameter.

Mechanisms of Deposition

Particle deposition in the human respiratory tract takes place primarily by three mechanisms. Inertial impaction causes filtering of particles according to their aerodynamic size and velocity. This mechanism of deposition is especially important in the upper and central airways. In particular, oropharyngeal deposition increases approximately in proportion to the particle velocity and the square of its aerodynamic size. Therefore, particles with large aerodynamic diameters, especially if they are inhaled rapidly, will not be delivered to the lung for absorption. Gravitational sedimentation and diffusion are important for deposition of particles in airways and the alveolated regions. The extent of deposition by both of these mechanisms increases with breath-holding. Particles with aerodynamic diameters around 0.5 μm are neither small enough to deposit rapidly by diffusion, nor large enough to be deposited without prolonged breath-holding by sedimentation. It would be also practically quite difficult to produce submicron size aerosols containing proteins and peptides. The aim is therefore to produce a slow, moving aerosol cloud with drug containing particles in the size range 1–3 μm to minimize oropharyngeal deposition since peptides or protein are poorly absorbed from this region. Indeed, deposition of inhaled particles in this part of the human respiratory tract has been the primary cause of inefficiency and poor reproducibility of pulmonary delivery in the past (6).

Importance of the Mode of Inhalation on Deposition

The nose is a much better particle filter than the mouth, and oral inhalation is therefore preferred for more efficient and reproducible delivery to the lung.

We have already discussed the impact of inspiratory flow rate on deposition: the faster the subject inhales, the more material is deposited at bends and bifurcations in the upper and central airways, and the less material reaches the deep lung. Inspiratory flow rate may also affect the performance of inhalation systems; this is particularly important in passive dry powder inhalers in which the energy of breathing is utilized to deagglomerate the formulation (35). Thus, for such systems, there is a

contradictory requirement for the need to use high inspiratory flow rate to achieve fine particle size for deep lung delivery and yet to have sufficiently low inspiratory flow rate to avoid impaction before the drug entry to the absorptive surfaces devoid of mucociliary clearance.

It would be also expected that to get to the deep lung, the drug containing aerosol needs to be inhaled at the beginning of the inspiration, starting from “empty” lung since there is relatively little mixing of an inhaled “bolus” with the rest of the inhaled air (36). Therefore, the preferable maneuver is a full exhalation followed by a slow, deep inspiration, and finally a breath-holding period. In practice, a few seconds appears to be adequate for practically complete deposition of particles in the optimum size range for “deep lung” delivery.

Recurrent training of patients taking inhalation therapy is required to achieve reproducible delivery of inhalation therapy. Electronic systems with visual feedback to the patients have been developed to assist the patients to use their drug product correctly (36–38).

DETERMINATION OF PULMONARY ABSORPTION

The structural and functional heterogeneity of the respiratory tract also leads to the finding that generalization of results of pulmonary absorption experiments can only be made if the regional deposition of the materials in the respiratory tract is also determined. Intratracheal administration facilitates quantitative deposition of the material whose absorption properties are being studied. Several variants of this technique exist: some of them require surgical procedure (e.g., incision that exposes the rodent trachea through which a needle with the drug formulation is injected), some utilize the insertion of a cannula or a microspray nozzle into the animal's trachea. However, the material thus deposited is not distributed to the same extent throughout the respiratory tract as when given by inhalation of aerosols (17–20).

Lung cell cultures can provide mechanistic insights (39) but they do not represent the complexity in the delivery and disposition of drugs in the human respiratory tract. Perfused lung organ studies provide the next level in complexity (40). Various animal models have been used with the view to predict quantitatively absorption of peptides and proteins from the human lungs. However, due to the major differences in the anatomy and physiology of respiration in primates, the predictive power of these models is quite limited as evidenced by the data in Fig. 2. (Animal models are, of course, essential in the assessment

of safety and they can provide valuable mechanistic information.)

The use of drugs in conjunction with gamma radiation emitting radiolabels that facilitate noninvasive measurement of regional doses is the favorite way to investigate mechanistic aspects of pulmonary absorption. The drug can be radiolabeled directly, or, more often, the radiolabel and drug are physically mixed. It is important to prove that the radiolabel does not affect the performance of the drug product either chemically or in terms of its emitted dose (ED) and particle size distribution (PSD). Further, the functional performance, ED and PSD, measured *in vitro* with the drug assay and the radiolabel assay should be the same. This method can thus determine both the total dose to the lung as well as its distribution in various parts of the respiratory tract, both in animal (17, 18, 41–42) and humans (22, 43).

STABILITY ISSUES

A key issue for effective protein and peptide absorption is the preservation of biochemical and structural integrity during the preparation, storage, and aerosolization of the drug molecule. Many proteins and peptides are available as stable aqueous formulations for delivery by injection. However, the process of aerosolization can cause damage to the active molecule. The generation of small droplets provides a vast increase in the air-liquid interfacial area, which may cause unfolding of proteins followed by aggregation. This is particularly likely to happen for hydrophobic proteins that undergo multiple recirculation in jet nebulizers (44) or during spray-drying (45) and may be prevented by addition of suitable surfactants (42). Single-pass systems that form aerosol by extrusion of the solution through a fine nozzle (46) do not appear to cause protein denaturation, in contrast to conventional nebulizers that involve multiple recirculation of the solutions. Thermal denaturation can occur also during the high temperature spray-drying or with some ultrasonic nebulizers that warm the solution for nebulization during their operation (47). Freeze-dried parenteral protein preparations are typically unsuitable for delivery by inhalation for at least two reasons: they often contain excipients such as citrate that could cause irritation if inhaled in sufficient quantities. The freeze-dried materials form cohesive powders that do not lend themselves to be dispersed into respirable particles. Spray-drying has been employed to make respirable protein powders (48, 49). Judicious choice of the quality and quantity of excipients used in dry powders is required to minimize the potential

for adverse reactions, especially in subjects with compromised airways (50, 51). Avoidance of excessive temperature and the use of excipients such as certain sugars in spray-dried formulations may prevent the formation of potentially immunogenic protein aggregates and loss of activity. The nature of the formulation can also affect the quality and physical stability of the particles carrying the peptide or protein. These particles need to flow well during the filling operation and to provide high emitted doses, and they also have to disperse readily into particles with the right aerodynamic diameters. The appropriate balance thus needs to be struck between the chemical stability of the biologic and the physical stability on storage that preserves the solid state form and protects the particles against aggregation and loss of dispersibility into respirable particles (48, 51).

CASE STUDIES WITH SPECIFIC MOLECULES

Insulin

Pulmonary delivery of insulin for systemic absorption in the treatment of diabetes has been studied extensively since the early days of insulin discovery almost a century ago (1). Colthorpe et al. (17) and Pillai et al. (42) demonstrated in rabbit and monkey models, respectively, that the deeper into lung the dose of insulin was delivered, the higher was the bioavailability. The work of Laube et al. (43) showed the need to achieve deep pulmonary deposition of this molecule for efficient absorption in humans. Hand-held liquid and dry powder delivery systems have been developed to generate insulin-containing aerosols with the majority of the particles in the aerodynamic size range 1–3 μm . The relative bioavailability compared with subcutaneous injection based on the insulin contained in the dosage form was $\sim 11\%$ (52) for the dry powder system and $\sim 16\%$ (53) for the aqueous-based bolus delivery system. The reproducibility of pharmacokinetic and pharmacodynamic parameters following pulmonary administration was reported to be similar to subcutaneous delivery. The total lung volume at the end of inspiration was reported to have a major effect on insulin absorption, with deep breath leading to a significantly faster absorption than a more shallow inhalation (14, 23). This suggests that in addition to the inspiratory flow rate and inspired volume at the time of insulin delivery by inhalation, total lung volume may need to be controlled, too, for efficient and reproducible delivery of this molecule that has a rather narrow therapeutic index.

Human Growth Hormone

Wall and Smith (54) reviewed the literature data on pulmonary absorption of recombinant human growth hormone (rhGH) in animal models. A wide range of absolute bioavailability ranging from 3–36% was found. Bioavailability of hGH delivered to the lung increases dramatically the deeper into the lung the formulation reaches (18). Since rhGH is a growth factor, at least theoretically there is a possibility that its delivery to the lung could cause unwanted growth of some lung tissues. Aerosolized delivery of rhGH for 11 days induced body growth of hypophysectomized (“hypox”) rats but caused no abnormal lung growth in these animals. A mild immune reaction was seen in the lung, which was not present, when aerosolized bovine growth hormone (bGH) was used instead of hGH. bGH has a much closer amino acid sequence to rat growth hormone than hGH and is thus not significantly immunogenic in this species. Interestingly, IgG titers following subcutaneous administration of hGH were higher than those in the inhalation group and no IgE antibodies were found in the course of inhalation treatment in rats. While total body weight increased in the hypox rats treated with aerosolized hGH, the ratio of lung weight to total body weight did not change. GH receptors are present in many types of cells, but no GH receptor message was found on the “air side” of rabbit lung (55).

Luteinizing Hormone Releasing Hormone (LH-RH)

LH-RH analogs were extensively researched (10). The nonapeptide leuprolide in particular underwent extensive development. Absorption was very significantly dependent upon the depth of deposition of the material in animal models: essentially quantitative absorption was found when the intratracheal administration in beagle dogs was done 20–25 cm downstream from epiglottis. Leuprolide acetate suspension aerosols were prepared in chlorofluorocarbon propellants. No adverse reactions were found in association with multiple dosing of these formulations in beagle dogs. Bioavailabilities ranging from ~7–26% found in human studies with these metered dose inhalers, in good agreement with the general fraction of the nominal metered dose that reaches the lung from this type of aerosol delivery system (56).

Soluble Recombinant Interleukine-4 Receptor

(IL-4R) was delivered by nebulization to Cynomolgus primates (41). The peak serum levels were reached after

9.5 h. Absolute bioavailabilities close to 30% were measured.

Interferons

Niven et al. (13) studied the absorption of consensus interferon in rodent models. Absolute bioavailabilities approaching 70% were found for the pulmonary route, with evidence of biologically active molecules being absorbed. Mackay et al. (5) compared the absolute bioavailabilities of a hybrid BDBB alpha-interferon in the rat following different routes of administration and found 0.75% for colon, 0.014% for buccal, 0.5% for nasal, and 4.5% for the lung (via intratracheal instillation). Pharmacokinetics of inhaled alpha-interferon was followed in several human studies: Kinnula et al. (57) reported detectable levels with high doses and systemic adverse reactions indicative of biological activity of the absorbed cytokine. In a related study (58), it was observed that the recombinant version of the molecule seems to be less well absorbed than the natural interferon. Differences in metabolism between the natural and recombinant alpha-interferon were also found in a perfused rabbit lung model (59).

Calcitonin

The salmon form of this 32-amino acid non-glycosylated polypeptide is available as a nasal spray with a bioavailability in humans of ~3% (60). Mackay et al. (5) reported that the absolute bioavailabilities of human calcitonin across the colon of rat and man, and the lung (via intratracheal instillation) of rat, were 0.9, 0.15 and 36%.

Human Recombinant Granulocyte Colony Stimulating Factor

The systemic bioavailability of recombinant human granulocyte colony stimulating factor (rhG-CSF) based on the amount reaching the lung lobes following intratracheal instillation to the hamster was estimated to be 62% relative to intracardiac administration. Remarkably, about 20% of the absorbable dose of this 18.8-kDa protein was present in serum within 6 min postadministration. The biological activity of the absorbed material was confirmed by the increase of the circulating white blood cells (20). No apparent toxicity was found even on repeated dosing in animals with this protein. Pegylated forms of this molecule were also found to be well absorbed. The rate of and extent of absorption were very much affected by the mode of administration (instillation, powder insufflation, and aerosol administration), reflecting

Table 1

Physiological parameter	Breathing maneuver for optimum peptide and protein absorption
Lung volume prior to inhalation	Full exhalation
Volume inhaled at the time of actuation of aerosol delivery	Minimum volume inhaled prior to actuation of drug delivery
Inspiratory flow rate	The minimum flow rate consistent with acceptable performance of the aerosol delivery device
Total volume inhaled during delivery	Close to vital capacity (shown to be important for insulin)
Respiratory pause between inspiration and exhalation	Several seconds (minimum time to be determined by experimentation)

the differences in the penetration of the material into the deep lung.

PULMONARY ABSORPTION OF PEPTIDES AND PROTEINS INTENDED FOR LOCAL EFFECTS IN THE LUNG

Numerous proteins have been investigated for administration to the respiratory tract to treat local disease (61). In some of these investigations, absorption into the systemic circulation was also followed. These results have their utility when absorption of similar molecules is being considered for the purpose of systemic delivery or to estimate the systemic exposure of locally delivered macromolecules for safety purposes.

Cyclosporine

Cyclosporine is an endecapeptide isolated from fungi. It is an immunosuppressive used to prevent rejection in organ transplantation. Studies have been carried out to investigate the effectiveness of inhalation of this compound in patients receiving lung transplants. Very rapid peak plasma levels were observed followed by a slow phase but the interpretation of this behavior is compromised by the low aqueous solubility of this compound (62).

Alpha-1 Antitrypsin

(A1AT) has been used in injectable form for the treatment of hereditary A1AT deficiency that markedly increases the risk of development of emphysema. Absorption of aerosolized human plasma and recombinant A1AT into the lymph and blood was studied in sheep and humans (63). Human plasma A1AT was found in the sheep blood and interstitial lymph at concentrations ~1/1000 of that in the

alveolar epithelial lining fluid (ELF). The recombinant human A1AT is nonglycosylated and has a terminal methionine residue. In the sheep model, this molecule disappears from the alveolar fluid faster than the human plasma A1AT, with the lymph levels around 10% of ELF and blood levels about 10% of the lymph. The recombinant form was also detected in the blood 24 h after administration to humans.

Recombinant Human Deoxyribonuclease

(rhDNase) has been approved for administration by inhalation for the treatment of cystic fibrosis (9). Bioavailability <15 and <2% in rodents and monkeys respectively was found with this molecule in single-dose studies. In humans, the serum levels of rhDNase following nebulization did not lead to a significant increase above the baseline levels of the endogenous rhDNase.

Anti-IgE

Elevated levels of immunoglobulin E (IgE) in the respiratory lumen and blood are associated with allergic asthma. Sweeney et al. measured concentrations of a monoclonal humanized antibody against IgE (E25) in the blood and bronchoalveolar lavage of different animal species and humans following administration into the respiratory tract. Only small quantities of the antibody were absorbed over a period of several days. The authors suggested that the mechanism of uptake was nonspecific (64).

SUMMARY

While there are no currently approved therapeutic protein or peptide products for delivery via the pulmonary route

into the systemic circulation, the data on the efficiency, reproducibility, and safety of molecules such as insulin are particularly encouraging. From a molecular perspective, there is a general trend in the reduction of the rate and extent of absorption with increasing molecular weight, but predictive theories are lacking due to our poor understanding of the complexity and multitude of channels of entry of drugs from the respiratory tract into the systemic circulation. The aerodynamic size distribution is a key parameter affecting the regional distribution, and hence the absorption, of macromolecular drugs from the lung. The synchronization of optimum breathing and aerosol delivery appears to be a prerequisite for efficient and reproducible delivery; the key parameters to control are listed in Table 1.

Relatively little work has been done so far on the control of the rate of absorption of macromolecules from the lung with modified release formulations. Slow pulmonary absorption of insulin in the rat was reported when the drug was encapsulated in polylactic glycolic acid spheres (65). The long-term safety of such long-acting excipients needs to be investigated: in contrast to small molecules, it would be expected that significant accumulation of these materials could occur on multiple dosing (16).

INTEREST AND RATIONALE

An increasing number of peptides and proteins will be introduced into therapeutics in the forthcoming years. The gradual maturation of the biotechnology industry has led to many advances, not the least of which is that it is now possible, for the first time, to produce large quantities of highly pure peptides and proteins. However, their potential usefulness as therapeutic agents will be much enhanced if constraints imposed by the parenteral route of delivery, the only one currently available for most of these agents, can be overcome. The design of successful dosage forms for the delivery of these complex biotechnology products by alternative routes is a challenging objective for the pharmaceutical scientist.

Possible nonparenteral routes for the delivery of peptide and protein drugs include the nasal, oral, transdermal, buccal, ocular, rectal, and vaginal pathways (1–3). In general, the primary advantages of these strategies over parenteral delivery are the relatively noninvasive nature and simplicity of administration. However, it goes without saying that these alternative routes are generally much less efficient than an injection (whether intravenous, intramuscular, or subcutaneous) with frequently very low bioavailabilities.

Transdermal delivery has attracted considerable interest as a route for administering peptides and proteins. Among its appealing features, the transdermal path a) avoids the hepatic first-pass effect and gastrointestinal breakdown, a very important factor for these metabolically very fragile drugs; b) provides controlled and sustained administration, particularly suitable for the treatment of chronic disease; c) reduces side-effects, often related to the peak concentrations of the circulating agent; d) enables self-administration and improves patient compliance, due to its convenience and ease of use; and e) permits abrupt termination of drug effect by simply removing the delivery system from the skin surface (3).

Because the skin has a relatively low proteolytic activity compared with other tissues, the poor inherent skin

permeability of the peptide drugs is the prime limiting factor for their delivery by the transdermal route (1). Generally speaking, peptide and protein drugs are polar and compared with “normal” drugs, of high molecular weight. Such molecules diffuse poorly, as a result, across the skin, making the use of an appropriate enhancement strategy (as we shall see) obligatory. Several approaches being investigated to enhance the transdermal absorption of peptide and protein drugs are reviewed in this chapter. These include the use of chemical penetration enhancers, iontophoresis, the application of transient high-voltage pulses (electroporation), the use of ultrasound (sonophoresis), and various, so-called minimally invasive strategies.

SKIN BARRIER FUNCTION

Stratum Corneum and Routes of Passive Permeation

The remarkable barrier function of the skin is primarily located in the stratum corneum (SC), the thin, outermost layer of the epidermis (4). The SC consists of several layers of protein-filled corneocytes (i.e., terminally differentiated keratinocytes) embedded in an extracellular lipid matrix. Attached to the outer corneocyte envelope are long-chain covalently bound ceramides that interact with the lipids of the extracellular space. These lipids are composed primarily of free fatty acids, ceramides, and cholesterol arranged in multiple lamellae (5). Passive permeation across the SC is believed to occur primarily via the intercellular lipid pathway (Fig. 1a), which constitutes the only continuous phase through the SC (6). Evidence for this deduction is provided by the temperature dependence of SC water permeability (7) and the remarkable correlation between water transport and the degree of disorder of the intercellular lipids (4). In addition, several imaging techniques, using various different tracers have been used to directly visualize permeation via the intercellular path (6, 8). Further, it has recently been concluded that the

Fig. 1 Routes of passive permeation across the stratum corneum (SC): (a) intercellular lipid pathway; (b) appendageal transport; and (c) transcellular path.

barrier function of the SC is rather uniformly distributed across its entire thickness (9). Appendageal transport through hair follicles and sweat glands is another potential route, these structures offering “shunt” pathways across the continuity of the SC (Fig. 1b). Visualization of appendageal transport has been accomplished both for passive diffusion and for percutaneous transport enhanced by one means or another (e.g., iontophoresis) (6, 10). Passively, while it has been postulated that the appendageal structures dominate initially, their contribution to total steady-state transport is believed to be rather small due to the small area available relative to the entire surface of the skin (10, 11). A third possible route across the SC is the transcellular path (Fig. 1c). However, despite its favorable surface area and short pathlength (compared with the tortuous intercellular route), no evidence exists in support of molecular permeation by this way; indeed, the implausibility of the route has been demonstrated by certain authors (8, 12).

Structure–Permeation Relationships: Application to Peptide Absorption

Most structure–permeation evaluations of transdermal transport indicate the strong relationship between a chemical's permeability coefficient across the skin (K_p) and its lipophilicity (13–15). Potts and Guy (14) analyzed a diverse database of skin penetration data, comprising 91 compounds (15) and developed a simple relation indicating that K_p depended only on lipophilicity, as

measured by the chemical's octanol–water partition coefficient (P), and molecular weight (MW):

$$\log K_p(\text{cm/sec}) = -6.3 + 0.71 \log P - 0.0061 \times \text{MW}$$

However, for compounds of high lipophilicity, the algorithm needs to be modified (16) to account for the fact that these substances may become transport-limited not by their diffusion through the SC, but rather by their ability to partition out of this membrane into the underlying aqueous, viable epidermis. At the opposite end of the lipophilicity scale, the very small $\log P$ values of polar compounds, including peptide and proteins, of course, many of which retain a charge (or multiple charges) over a broad pH range, mean that their K_p values are extremely small and, hence, their inherent transdermal fluxes, without a suitable enhancement technique, are not therapeutically useful. As a general point, it must be emphasized that no matter what one might do to enhance transdermal delivery, the route remains useful exclusively for compounds of high potency (including peptides).

STRATEGIES FOR THE TRANSDERMAL DELIVERY OF PEPTIDES AND PROTEINS

Passive Delivery and Chemical Enhancement

It is widely accepted that the two most important physicochemical parameters that determine a molecule's skin permeability are a) its lipophilicity, with a \log (octanol/water partition coefficient) value of 2 being quite favorable, and b) its molecular size—smaller compounds permeating better than big ones (14). Thus, it is no surprise that the passive transdermal delivery of peptides and proteins, which are typically either very polar (or charged) and/or of high molecular weight (>1000 Da), is extremely inefficient and rarely results in fluxes, which would elicit significant therapeutic effect.

Consequently, a number of enhancer formulations have been considered in an attempt to improve peptide transport across the skin. These vehicles include, as we shall briefly discuss, either well-known chemical promoters or combinations thereof, peptide metabolism inhibitors, or colloidal (principally liposomal) structures. Table 1 summarizes much of the available literature. Before addressing specifically certain examples of the results obtained, it is worth noting that, although increased peptide transport has been possible, little attention has been focused upon the effects of the enhancer formulations on the skin (such as irritation and, in consequence, long-term tolerability) nor

Table 1 Effect of chemical enhancers and vehicle composition on the transdermal passive delivery of peptide drugs

Peptide	Vehicle	Skin model	Comments	Ref.
A. Passive + chemical enhancer Ocreotide [NL ⁴ , D-Phe ⁷]- α -MSH (melanotropic peptide analog)	40% EtOH; 1% Decylmethyl sulfoxide in 40% EtOH; 50% Dimethyl sulfoxide 26% PEG 400; 74% PEG 3350	Hairless mouse skin; heat-separated human epidermis Mice shaved skin	In vitro; clinically relevant delivery In vivo; follicular melanogenesis induction	(17) (18)
	Azone; PEG	Mouse skin; rat skin Dermatomed human skin Human SC and de-glycerinized dermatomed skins (Dutch Burns Society)	In vitro; delivery through mouse but not through rat skin In vitro; delivery measured In vitro; enhancers required for relevant delivery	(19) (20) (21)
	<i>n</i> -Decylmethyl sulfoxide (10 mM) + metabolism inhibitors (piromycin, amastatin) Sodium laurylsulphate (0.9 to 19.2 $\times 10^{-3}M$)	Hairless mouse skin Rat shaved skin	In vitro; study of the metabolism; coadministration of inhibitors to increase flux In vitro; effect of pH and peptide concentration; no effect of enhancer found	(22) (23)
	Azone (3–25%); dimethyl sulfoxide; DMAC; NNDMT; transcutoil; labrafil	In vitro hairless mouse/rats; in vivo rats; “clipping” hair shaved	Best results with Azone (clinical effect in vivo: reduction of urine volume and increase in urine osmolality)	(24)
	Carbopol gel + different enhancers and protease inhibitors: e.g., bile salts, gabexate, bestaline, OG, OTG.	Shaved rat	In vivo; effect of protease inhibitors; observation of the hypocalcemic effect	(25)
	Carbopol gel; vitamin D3 + Estradiol + OTG + aurocholate	Rats (suffering experimental osteoporosis); shaved skin Nude mouse; dermatomed human skin; snake skin	In vivo; efficiency in treating experimental osteoporosis in rats In vitro	(26) (27)
	2% HPMC; EtOH:water (4:1) + enhancer: menthol (1-2%); camphor (2%); methyl salicylate; (2%); lauric acid (2%); decanoic acid (2%); 20–80% ethylalcohol; 10% urea			
	PG, azone; glyceryl mono-oleate; EtOH; β -cyclodextrin In PBS solution	Dermatomed human and monkey skin Rat shaved skin	In vitro; 80 h permeation time Prodrug approach: Permeation of parent compound and acylated derivatives.	(28) (29)
	B. Passive + colloidal vehicle Oil/water emulsion liposomes	Hairless mouse skin	In vitro; stripping procedure; cyclosporin accumulated; high cyclosporin into the skin	(30)
	Liposomes Liposomes	Human skin grafted in nude mice Dermatomed human skin	In vivo; measurement of ICAM-1 induction In vitro; measurement of bio-activity of the transported peptide (10% active)	(31) (32)
Nafarelin Tetragastrin	Liposomes + iontophoresis Microemulsion liquid crystals	Human skin Stripped rat skin	In vitro In vitro	(33) (34)

Abbreviations: EtOH (ethanol); PEG (polyethylene glycol); SC (stratum corneum); DMAC (dimethyl acetamide); NNDMT (*N,N*-dimethyl-*m*-toluamide); OG (*n*-Octyl- β -D-glucoside); OTG (*n*-Octyl- β -D-thiogluconide); HPMC (hydroxypropylmethylcellulose); PG (propylene glycol); PBS (phosphate buffer solution); ICAM-1 (intercellular adhesion molecule-1).

has the fact that animal models of questionable relevance (e.g., the shaved skin of hairy rats, notorious for their higher skin permeability relative to man even in the absence of penetration enhancer) have been used. To illustrate the “gap” between laboratory and reality, with respect to the feasibility of some enhancer vehicles proposed, one can cite the delivery of octreotide from a formulation containing 40% ethanol and 50% dimethylsulphoxide (17) and the delivery of leuprolide from a 4:1 v/v ethanol–water solution to which various known chemical skin permeation enhancers had been added (27). It is not foolhardy to predict that both these approaches would cause local irritation of the skin *in vivo* in man and that their chronic use would be precluded.

Among the more interesting and reasonable results published are a series of studies demonstrating the delivery of the melanotropic peptide [Nle⁴, D-Phe⁷]- α -MSH across mouse and human skin from a relatively mild formulation consisting of 1:3 v/v PEG 400-PEG 3350 (18–20). *In vivo* across shaved mouse skin, in fact, it was possible to show induction of melanogenesis (18). Unfortunately, however, these data remain at best semiquantitative: no actual flux values were measured precluding comparison with other work in the field.

Positive pharmacological results have also been observed following the delivery of the relatively high molecular weight peptide, elcatonin (3363 Da, a calcitonin analog) across shaved rat skin *in vivo* (25, 26). Hypocalcemia was documented together with a beneficial effect on this animal model of osteoporosis. Successful formulations included taurocholate and peptidase inhibitors, such as gabexate and bestatine. Another approach has involved the use of lipophilic prodrugs of the peptide tetragastrin but, in this case, one has to ask whether the improvement in delivery is sufficient to warrant the additional regulatory complexities concomitant with the prodrug strategy (29).

The largest body of recent work in this area has involved the use of colloidal carriers, in particular liposomes (see Table 1); comprehensive reviews of this research can be found elsewhere (35–37). A general observation on the information published to-date is that the amount of lipid formulation applied is often very high when compared with the quantity of intercellular SC lipid in the treated area of the skin. That such liposomal formulations can significantly perturb (or, perhaps, overwhelm is a better word) normal barrier function is not too surprising, especially if the exogenous lipids employed can mix efficiently with their endogenous counterparts (30, 32, 38); this may explain why liposomes based upon lipid mixtures that mimic the composition of those in the SC are sometimes useful.

These lipid-based systems have been used to deliver peptides for both dermatological and systemic therapy. In the former case, the administration of cyclosporin (CSA) to treat psoriasis has been considered, with the idealistic objective of somehow localizing the drug in the skin while minimizing its entry into the systemic circulation (30). *In vitro*, from the lipid-based vehicles, almost no CSA permeated into the receptor phase in conventional diffusion cell experiments. However, this result was not different from the “control” formulation, which simply contained CSA in 40% ethanol. Much of the drug (>60%), and the lipids from the liposomal-based formulation, were actually found in the SC at the end of the experiment. In the same category, a particularly well-conducted study considered the delivery of γ -interferon from liposomes across human skin *in vitro* (32); topical application of γ -interferon has been proposed for the treatment of atopic dermatitis and keloidal scarring. Initial investigation with γ -interferon suggested a quite short lag-time (on the order of an hour) but that the liposomally delivered peptide had lost most of its biological activity (32). In a subsequent series of experiments, the work was extended to an *in vivo* model of human-skin grafted nude (athymic) mice (31). It was found that the γ -interferon delivered in this case retained its biological activity and promoted epidermal ICAM-1 induction (Fig. 2).

With respect to systemic delivery of peptide and protein drugs encapsulated in lipid-based carriers, Cevc et al. (39) have investigated the transdermal delivery of insulin encapsulated in “elastic” liposomes (TransfersomesTM), which differ from conventional liposomes in that a surfactant is added to the formulation (e.g., sodium cholate, sodium dodecyl sulfate, or bile salts). A dose-dependent systemic hypoglycemia has been reported in human volunteers following topical application of such an insulin formulation, over an area of 45–90 cm²; the effect was typically 25–45% of that following a subcutaneous injection of the same formulation. The authors claim that this outcome is not the result of the disrupting effect of the ethanolic (10%), surfactant-rich formulation on the integrity of the skin barrier, since “rigid” liposomes (ethanolic liposomes without bile salt) and insulin/mixed micelles (which contain the highest bile salt concentration of all formulations studied) had no significant hypoglycemic effect. On the contrary, they argue that the specifically elastic properties of the transfersomes are the crucial features that allow the lipid vesicle to carry the encapsulated agent across the skin (39).

Finally, the topical application of proteins to intact skin as a noninvasive method for immunization and vaccination has been described recently. The cholera toxin (86 kDa) has been shown to induce significant antibody production when

topically applied to shaved, previously hydrated, mouse skin (40). The cholera toxin has also been shown to act as an immunizing adjuvant, that is, it enhances immune responses against less potent antigens, such as diphtheria toxoid, and tetanus toxoid, when coadministered topically (40). A subsequent report identified several other bacterial products that also elicit adjuvant properties, but having less risk of toxicity and reduced secondary effects than cholera toxin (41). Transdermal immunization has also been obtained in mice with large proteins, such as the gap junction protein, encapsulated in lipid vesicles (42, 43). A more sophisticated approach, the transdermal delivery of an antigen-encoding plasmid, which induces *in vivo* the production of the antigen protein, has also been investigated and will be discussed later in this chapter. Overall, the future development of noninvasive, easily administered vaccines is of much interest, particularly for massive immunization programs in developing countries, where the lack of trained personnel capable of performing accurately repeated injections (which are far from welcomed) poses a significant barrier to prophylactic health care.

Iontophoresis

Iontophoresis is a noninvasive technique that uses a mild electric current ($<0.5 \text{ mA/cm}^2$) to facilitate the transfer of molecules across the skin (Fig. 3). The frequently polar and/or charged nature of biotechnology drugs makes them

potentially well-suited candidates for electrically controlled drug delivery across the skin (44, 45). Indeed, as we shall see, human studies using iontophoresis have already demonstrated the safe, effective, and reproducible delivery of intact peptides to the systemic circulation. Specific accomplishments for certain peptide iontophoretic applications of particular note to date are: a) that steady-state plasma levels can be achieved relatively rapidly and then maintained for reasonably prolonged periods of time, until the current is stopped and b) that the current profile can be adjusted to change the delivery profile, and hence to preprogram perhaps the more complex dosing regimes required. In addition, for two small nonpeptide drugs, at least, small easily portable and integrated iontophoretic devices are in advanced stages (Phase III) of development.

Iontophoresis enhances drug delivery across the skin by two principal mechanisms: electrorepulsion and electroosmosis (46) (Fig. 4). Electrorepulsion is the direct effect of the applied electric field on a charged permeant. Practically speaking, this means, for example, that a positively-charged (cationic) drug is formulated at the anode and, upon applying the electric field, is repelled toward and through the skin. The drug ion acts, therefore, as a charge carrier in the electric circuit. However, the fraction of the total charge delivered by the power supply that is carried by the drug may be quite small and, for larger peptides, rarely approaches even a few percent. This is because there may be competing (e.g., buffer, electrolyte) cations in the formulation and there are always competing anions (especially Cl^-) carrying a significant amount of charge out of the skin toward the anode (Fig. 3). Formulations must therefore be optimized to minimize the presence of competing ions, at least in the direction from the skin surface into the body. The second mechanism, electroosmosis, results from the fact that the skin supports a net negative charge at physiological pH (47, 48) [the pI of the human skin has been shown to be within the range 4.5–5 (47)]. Imposing an electrical potential gradient across a charged membrane produces a convective solvent flow in the direction of counterion transport (i.e., from anode-to-cathode in the case of skin). This solvent flow therefore augments the electrotransport of cationic, and very polar, yet neutral, compounds, while acting against the electromigration of anions (Fig. 4).

The relative importance of electrorepulsion and electroosmosis has been the subject of much investigation (49–58). It is generally agreed that small, highly mobile ions (e.g., Na^+ , Cl^- , small charged amino acids) are principally moved across the skin by electrorepulsion, whereas large, bulky species carrying only a fraction of the charge passing across the skin can only be transported by electroosmosis (Fig. 5). As molecular size increases for

Fig. 2 ICAM-1 production after topical application of gamma interferon to a human skin graft on nude mice. One dose ($100 \mu\text{l}$) of a liposomal (20 mg/ml lipid) or aqueous (phosphate buffered saline) formulation was applied daily for three days. Active formulation contained 0.51 mg/ml gamma interferon. Placebo liposomal formulations contained no added protein. Significant differences (active versus placebo) are indicated by asterisks (*). (Redrawn from data in Ref. 31.)

Fig. 3 Schematic representation of iontophoresis. Two electrode chambers, connected to a power source, are placed in contact with the skin. Upon application of the electric field, drug ions are repelled from the electrode of similar polarity (in this case, cations are repelled from the anode). This electrorepulsion (ER) also imposes “inward” motion on i) other cations present in the anode formulation, and ii) the “outward” transport of anions (e.g., Cl^-) from within the skin. At the ‘non-working’ electrode (in this case, the cathode), negative anions from the electrolyte are driven into and through the skin, while cations (e.g., Na^+) are “extracted” from the tissue. The direction of the electroosmotic flow (EO) is also shown (see text for details).

cations, therefore, there will be a transition in the dominant mechanism from electrorepulsion to electroosmosis (50) (however, it should be said that where this transition occurs has not been fully defined); for anions, on the other hand, as molecular size increases, it is clear that, at the transition, the electrorepulsive contribution will be cancelled by electroosmotic convective flow going in the opposite direction (a fact that explains, at least in part, why insulin has proved a futile candidate for iontophoresis, see later). It should also be noted that there are examples of lipophilic cations (including peptides such as the LHRH analogs, nafarelin, and leuprolide) that can apparently associate strongly with the net negatively charged lipophilic skin, thereby neutralizing the anionic membrane, reducing its permselectivity and “turning off” electroosmotic flow, that is, the principal mechanism for the transport of such species (52–54, 58, 59).

The principal parameters controlling the iontophoresis of peptides/proteins can be summarized as follows:

- a. *Charge and pH:* As discussed above, in general, cationic species are delivered more efficiently than anions because they can take advantage of both electrorepulsive and electroosmotic mechanisms. Neutral species can also be enhanced if formulated appropriately at the anode. Increasing charge does not necessarily lead to

Fig. 4 Imposing an electrical potential gradient across a charged membrane produces a convective solvent flow in the direction of counter-ion transport (i.e., from anode-to-cathode in the case of skin). This electroosmotic effect (EO) adds to electrorepulsion (ER) to enhance the transport of cationic compounds during iontophoresis (4a) while acting against the electromigration of anions (4b).

better delivery (all other parameters remaining equal) primarily due, it is believed, to increased association with the membrane and, once again, reduced electroosmosis (48). The pH can be adjusted to optimize peptide stability, and sometimes to elicit better transport (because, e.g., the peptide shifts from being zwitterionic to cationic). However, pH cannot be adjusted too far i) because of concerns about irritation; ii) as this alters the inherent charge on the skin and, in consequence, its permselectivity properties.

- b. *Molecular size:* Simplistically, small charged molecules are better delivered than larger ones for reasons already articulated (Fig. 5). The absolute relationship is probably complex and may be difficult to deduce. For molecules delivered only by electroosmosis, transport should be somewhat independent of size (assuming that the dimensions of the drug never approach that of the pathway). Few studies have addressed this issue with respect to peptides/proteins specifically, although one investigation with poly-L-lysines of increasing molecular weight clearly indicated that a 4-kDa oligomer was more easily transported than the higher molecular weight (7- and 26-kDa) species (59).
- c. *Formulation:* The basic principles that apply generally to iontophoresis are especially relevant to peptides/

Fig. 5 Effect of molecular size on the relative importance of electrorepulsion (ER) and electroosmosis (EO) to the overall iontophoretic transport of cations and anions. Small, highly mobile cations are principally moved across the skin by ER. But, as molecular size increases, the fraction of charge carried by a cationic drug decreases, and the principal mechanism of transport becomes EO. For anions, on the other hand, EO is a negative contribution to the total flux and, once the molecular size reaches a critical value (m_c , completely cancels out the ER contribution to electrotransport (resulting in no net flux).

proteins. If the drug carries a measurable fraction of the charge being passed, then it makes sense to minimize the presence of competing ions in the formulation. Generally speaking, lower electrolyte levels also mean that electroosmosis is slightly higher too (49, 60). Moreover, stability issues may demand at least some level of background electrolyte and/or buffer; thus, polymeric buffers, for example, which are not necessarily competitive for charge-carrying, have been used to improve peptide delivery (61). Peptide stability during storage of an iontophoresis device has also been addressed (44, 62). Because iontophoretic formulations employ aqueous-based gels, there are, in particular, potential problems of hydrolysis. This issue has been attacked recently in the case of calcitonin by making a dry reservoir disc for iontophoresis (via compression of a mixture of freeze-dried peptide and gelatin), which is hydrated at the moment of use (62). Proof-of-concept of the idea has been achieved via the observation of a hypocalcemic response in rabbits (62). The other crucial component of the formulation, of course, is the electrode. In general, reversible, and especially Ag/AgCl, electrodes are preferred (63). These very stable and reproducible electrodes are well suited to iontophoresis and avoid the problems inherent in bare metal electrodes such as those made of platinum (in particular, the hydrolysis of water that leads to very

large changes in pH in the electrode formulations and/or demands the presence of a strong buffer) (64–67). A potential problem with the use of Ag/AgCl electrodes for peptide/protein delivery is that these drugs may be inactivated/degraded at the silver chloride surface (52, 68). It may be necessary, therefore, to devise a means to keep the drug away from the electrode (e.g., use of a semipermeable membrane or a salt bridge) (52, 68–70).

Now, we can summarize the principal teachings of the field with respect to peptide and protein delivery by iontophoresis. First, we consider the major results reported in vivo in different animal models. The tripeptide Thr-Lys-Pro has been iontophoresed into hairless rats (71). The apparent urinary excretion rate of the peptide following in vivo delivery was shown to be completely consistent with the measured flux in vitro. Pretreatment of rats with an iontophoretic current followed by passive application of the peptide, also resulted in enhanced delivery. No histological changes were detected following current passage in vivo, only slight reddening at the skin area under the electrodes. Notable delivery rates of octreotide (a somatostatin analog) were obtained following application of mild current densities ($50\text{--}150\text{ }\mu\text{A}/\text{cm}^2$) in vivo in rabbits (72). Increasing the intensity of the applied current elicited a proportional increase in peptide plasma levels, and drug input declined quickly upon current termination. On the other hand, another study, in which human calcitonin was delivered into hairless rats, showed that the lowering of serum calcium was not linearly dependent upon either current density or time of current application (73). Iontophoresis of LHRH has been investigated in vivo in pigs (74). Elevated LHRH concentrations were measured in the blood and concomitant increases in LH (luteinizing hormone) and FSH (follicle stimulating hormone) levels were observed, demonstrating that the hormone was delivered as the pharmacologically active species. Circulating levels of LHRH fell rapidly upon termination of iontophoresis. A larger peptide, growth hormone releasing factor, GRF (1–44) (MW 5040), was delivered by iontophoresis into hairless guinea pigs, resulting in steady-state plasma levels of $\sim 0.2\text{ ng/ml}$, which, in terms of flux, signifies that an input rate of $\sim 3.16\text{ }\mu\text{g/h}$ was achieved (75).

Secondly, we survey briefly the published findings on peptide/protein delivery by iontophoresis in man. Delivery of calcitonin gene-related peptide (CGRP) and vasoactive intestinal polypeptide (VIP) has proven useful in the clinical treatment of venous stasis ulcers (76). In 66 patients, 40 cm^2 iontophoretic patches were applied to intact skin in the proximity of the ulcer. Pulsed electric

current was delivered for 20 min. It was found that CGRP and VIP delivery was enhanced, as deduced from the clinical results, and that the electric current passing close to the ulcer area had a positive influence on the healing process. The iontophoretic delivery of leuprolide, a LHRH analog, has also been investigated in human subjects (77, 78). It was shown, following iontophoresis, that the observed increases in LH levels were comparable with those obtained after subcutaneous injection (77). The result was particularly remarkable considering the low current density delivered: that is, 0.2 mA over 70 cm² ($\sim 3.1 \mu\text{A}/\text{cm}^2$). Only 2/13 volunteers reported a tingling sensation during current passage while some erythema (which, nevertheless, resolved quickly after current termination) was observed at the electrode sites in 6/13 subjects. In a further report in human volunteers, the effect of formulation variables on the iontophoretic delivery of leuprolide (78) was examined. Highest transport was observed with the lowest leuprolide concentration investigated (Fig. 6). Changes in the ionic strength of the donor formulation had a greater effect on circulating leuprolide than on LH and testosterone levels, an observation that can be partially explained in terms of interindividual differences in the pharmacological response.

Lastly, we address insulin delivery to which much effort has been dedicated. While the insulin “spikes” required postprandially may be difficult to achieve with iontophoresis, the method may have the potential to mimic the physiological, nearly constant, basal secretion (1 IU/h) of the hormone, which is observed in the nondiabetic adult (i.e., a requirement that is not provided by intermittent subcutaneous injections) (79). A recent, excellent review (80) of the work performed (almost exclusively in animal models) concludes that while insulin iontophoresis can be sufficient to treat a small diabetic animal, the best deliveries achieved are still 1–2 orders of magnitude below that necessary to meet the basal secretion level in humans. It seems unlikely, therefore, that we will see an insulin iontophoretic delivery system on the market in the foreseeable future.

Electroporation

The application of high-voltage electrical pulses to the skin (so-called electroporation) is another approach that has also been used to increase peptide delivery across the epidermal barrier. Several reviews of the application of electroporation to increase transdermal delivery have been published within the last few years (81–85). Unlike iontophoresis, which employs small currents (0.5 mA/cm²) for relatively long periods of time (many minutes to hours), electroporation involves exposure of the skin to

relatively high voltages (on the order of 30–100 V imposed across the skin) for rather short times, typically one to several hundred milliseconds (85–87).

Mechanistically, as well, electroporation almost certainly differs from iontophoresis and an important effect involves the creation of new, low-resistance pathways through the stratum corneum. However, a detailed discussion of the physical impact of electroporation on skin barrier function is beyond the scope of this chapter, and the reader is referred to the literature for specific details (84, 86, 88).

In terms of peptide/protein delivery using electroporation, the most systematic work has been performed with the decapeptide LHRH (89, 90), and the ability of electroporation to induce its rapid delivery relative to “conventional” iontophoresis, in particular, has been clearly demonstrated (89). Specifically, using human skin *in vitro*, it was shown that a single electroporative pulse applied for 5 ms, followed by 30 min of iontophoresis at “normal” current densities, induced significantly higher delivery of LHRH than iontophoresis alone (89) (Fig. 7). An obvious allusion to an intravenous bolus followed by an infusion can be drawn from this work. Subsequently, in a sophisticated *ex vivo* model (the isolated perfused porcine skin flap), the pulsatile input of LHRH by electroporation was again examined, with the

Fig. 6 Serum leuprolide concentration and resulting circulating levels of luteinizing hormone (LH) in human volunteers following iontophoresis, as a function of drug donor concentration. Constant current (0.2 mA) was applied for 10–12 h. (Redrawn from data in Ref. 78.)

reproducibility of input following a second pulse of particular interest (90).

Another recent pair of investigations have examined the application of electroporation to enhance the delivery of cyclosporin for the treatment of psoriasis (91, 92). Compared to passive transport, single electroporative pulses resulted in up to a 60-fold enhancement in hairless rat skin permeability depending upon the vehicle used.

It must be said, however, that practical questions pertaining to electroporation are important barriers to its further development. Use of the high voltages required raises significant questions about safety, and how exactly electroporation would be practised in reality—only in hospital, or a doctor's office? What are the effects of electroporation on the skin? Acutely, within certain limits, the results are cautiously optimistic but, chronically, no one knows. And, from a marketing standpoint, electroporation must be grouped with other so-called “minimally invasive” technologies, which effectively remove the SC from the delivery equation. Under these circumstances, will electroporation compete with microneedles or “painless” injections? In short, electroporation has a long way to go before it can ever be perceived as a serious challenge to a simple injection.

Sonophoresis

The use of ultrasound (US) to enhance percutaneous absorption (so-called sonophoresis or phonophoresis) has been studied over many years, and is the basis of US propagation and US effects on tissue, and the use of US in transdermal delivery have been reviewed in detail (93–96). The proposed mechanisms by which US enhances skin penetration include cavitation, thermal effects and mechanical perturbation of the SC; that is, US acts on the barrier function of the membrane (96).

Sonophoresis has employed three distinct categories of US: “high-frequency” or diagnostic US (2–10 MHz), “mid-frequency” or therapeutic US (0.7–3 MHz), and “low-frequency” US (5–100 kHz). It appears, from a general overview of the literature, that the efficiency of US-mediated drug delivery depends on several factors, including US frequency, intensity (i.e., power per unit area), continuous versus pulsed mode, duty cycle, duration, coupling medium, and so on. The fact that very few studies have used common values for some or any of these parameters almost certainly accounts for the different and sometimes contradictory results in the public domain.

It should be noted that the US beam is made up of two components: the field closest to the transducer, and the field further away (the final, diverging conical part) (93). The relative size of these two zones, and their separation,

Fig. 7 Transport of LHRH (mean \pm SD) across human epidermis in vitro. A) passive flux, B) transport after 30 min of iontophoresis at 0.5 mA/cm²; D) transport after a single electroporative pulse (1000 V, 5 msec) followed by 30 min of iontophoresis at 0.5 mA/cm². The passive fluxes 2 h after termination of treatments B and D (columns C and E, respectively) are also shown. (Redrawn from data in Ref. 89.)

is a function of a) the US wavelength (i.e., frequency) and b) the transducer radius. The distribution of energy across these two regions is not uniform; indeed, near the transducer, it becomes quite complex, emphasizing again how small changes in experimental protocol between studies can lead to significantly different results.

From a practical standpoint, unlike the situation with iontophoresis, the transition from laboratory-size US equipment to a small, user friendly, and compatible device remains a challenging “scale-down” problem. Furthermore, as mentioned above, it appears that US acts on the skin barrier per se (while iontophoresis seems to exert its effects more specifically on the substance targeted for delivery) implying, therefore, that control of the enhancement technology continues to be an issue for the long-term, safe, and effective application of this method.

With respect to US-enhanced peptide and protein delivery, the most impressive results have been seen in the “low-frequency” domain. Tachibana et al. were the first to report the increased delivery of insulin across the skin of hairless mice (97) and rabbits (98) in vivo. Using US at 105 kHz (90 min, “pulsed”: 5 s on, 5 s off), significant insulin delivery and concomitant lowering of blood sugar were seen in diabetic rabbits (98) (Fig. 8). At a slightly lower frequency (48 kHz), a similar glucose-lowering effect was observed in the hairless mouse (97). Subsequently, Mitragotri et al. (99) described similar results in

hairless rats; in this case, the US frequency was 20 kHz, with a duration of application of up to 4 h, using 100 ms pulses at US intensities between 12.5 and 225 mW/cm² [lately, this intensity range has been corrected to 1.6–14 W/cm² (100)]. The same authors also reported that this low frequency US approach could be used to significantly enhance the delivery of interferon- γ (MW ~17 kDa) and erythropoietin (MW ~48 kDa) in vitro, that is, that macromolecules of much greater size could now be deliverable across the skin. It should be said, however, that no further data on these proteins has been reported since the initial publication in 1995 (99).

Additional work, however, has addressed mechanistic aspects of the effects of low-frequency US. Cavitation and thermal effects have been postulated and, to a certain extent, characterized (101–104), but further work is clearly needed to define exactly how US interacts with the skin barrier to increase its permeability.

Only one publication has presented data to support the idea that higher frequency (1 MHz) US can be used to increase peptide delivery across the skin (105). The enhanced transport of poly-L-lysine (MW = 4-kDa) across human epidermis has been reported, a finding completely at odds with the relatively modest action of US at this frequency on the percutaneous penetration of several “small” molecular weight substances (96).

Finally, in a related approach, Lee et al. have used photomechanical waves to enhance the skin delivery of 5-aminolevulinic acid (ALA), a δ -amino acid used in photodynamic therapy (106). The broadband, compressive waves appear to interact with tissues uniquely via mechanical forces. ALA delivery was shown to be proportional to the peak stress (388–503 bar) of the photomechanical wave applied.

In conclusion, despite the exciting low-frequency US results obtained, there remain important questions about mechanism, local skin effects and tolerability, reversibility, and ultimate practicability. These issues must be addressed before sonophoresis can move from research to development mode.

Gene and DNA Delivery to the Skin

The goal of gene therapy is to modify in some way the synthetic capability of a target cell, or population of cells, to provoke in situ the desired “therapeutic response” (107). While conceptually attractive, gene therapy is presently limited by problems associated with delivery; that is, how does one get the gene to the place where it can elicit its effect, and then how does one appropriately regulate the expression of the gene introduced?

Fig. 8 Change in blood glucose level following insulin delivery by ultrasound exposure to alloxan-diabetic rabbits. Filled bars (mean \pm SD) show the relative blood glucose level following ultrasound treatment for 1.5 h. The area of skin exposed was 7 cm²; the ultrasound frequency used was 105 kHz. Open bars indicate the corresponding control values. (Redrawn from Ref. 98.)

Gene delivery to, or via, the skin has three principal objectives (108): a) the treatment of primary cutaneous diseases and wounds, b) inducing skin cells to encode a protein which is subsequently released into the systemic circulation in a controlled fashion, and c) immunization. The first two instances involve a chronic delivery challenge, whereas immunization requires only acute exposure to the DNA involved.

Chronic delivery can be achieved, at least theoretically, either ex vivo or in vivo. In the former approach, cells are harvested from the skin by biopsy and cultured in vitro. Gene transfer is then effected in this in vitro setting (e.g., by electroporation) and the transfected cells are finally grafted back into the host (108). Clearly, this is a labor-intensive, complex, and expensive procedure. In the latter case, genetic material has been administered directly to intact skin, using either viral or nonviral vectors (e.g., adenovirus or modified herpes virus and DNA complexed with liposomes, respectively). In addition, a variety of physical methods have been investigated for DNA transfer into skin including direct injection (of both the naked DNA and plasmid associated with different vectors), particle bombardment (the “gene gun”), ultrasound, electroporation, and other so-called minimally invasive techniques (108–110). However, direct gene transfer in vivo, while attractive conceptually and technically easier to perform, has proven to-date to be rather inefficient and to result in only low and transient levels of gene expression (108).

DNA immunization consists of encoding an antigen in a plasmid, which is then transfected into cells in vivo. This results in expression of the antigen and the subsequent

induction of an immune response to the expressed protein (111). As the protein antigen is produced “naturally” in vivo, both cellular and humoral responses are developed. Skin has been proposed as an attractive site of immunization, and several skin cell types can become involved in DNA uptake, antigen expression and presentation. Quite recently, for example, in a mouse model, immunization has been reported following topical application of an aqueous solution of naked DNA (112). Given what one knows about the skin’s passive permeability to macromolecules, it is clear that only a very small quantity of DNA vaccine is required for immunization.

In summary, while the field of gene therapy in general is attracting widespread interest at this time, real successes at the level of the skin (beyond those positive results obtained in various model systems) are few and far between. It is clear, then, that considerably more work needs to be done. Detailed, and current, overviews of the state-of-the-art in cutaneous gene delivery can be found in Refs. (108) and (111).

Minimally Invasive Delivery Technologies

Finally, we consider the delivery of peptides and proteins across the skin by methods that physically circumvent the stratum corneum barrier in ways designed to be less invasive than the use of a classic needle and syringe. In these approaches, therefore, the excellent barrier function of the SC is acknowledged, and one turns one’s attention to bypassing this membrane in as least offensive a fashion as possible. This strategy for peptide delivery into the systemic circulation has been known for some time, however. The Matse Indians from Peru use one variation of this idea in shamanic hunting practices (113). Having obtained an extract from the skin of the frog *Phyllomedusa bicolor* (which contains ~7 wt% active peptides), a formulation is prepared and then applied to a small area of skin the epidermal barrier of which is first burned away with a smouldering twig. Within minutes of application, the treated individual experiences violent peripheral, gastrointestinal, and cardiovascular effects, followed by further remarkable central responses (increase in physical strength, resistance to hunger, thirst, stress, and so on).

Back in the world of intellectual property and patent protection, a number of sophisticated technologies have evolved in recent years and have often been applied to peptide and protein delivery objectives. Among the approaches used, one can cite ablation of the SC by laser radiation, by heat, and by erosion, as well as the use of particle bombardment and microneedles of various configuration. Some approaches are even suggested for

use in combination with other transdermal technologies, such as iontophoresis. As yet, none of these methods are approved clinically for peptide/protein delivery and all have yet to show real superiority over the gold standard injection via a conventional needle and syringe. An excellent review of the field has recently been written by Down et al. (114).

Mid-infrared laser ablation of the SC has been used to allow the transdermal delivery of interferon- γ (115). The mechanism by which this laser beam “explodes” away the SC is complex, yet quite reproducible and controllable, in that the number of laser pulses is correlated to the degree of SC damage (and hence to the peptide’s permeability through the tissue). Tissue destruction below the SC appeared to be minimal.

The MicroPorsTM technology (114, 116) consists of directing tightly focused thermal energy into the SC to create micropores. The skin is contacted by a wire mesh through which a current is passed that causes local heating sufficient to burn small holes in the barrier. Delivery of insulin by this approach has been suggested (116). A more macroscopic method to create an erosion in the SC is via “suction de-epithelialization” (117). Using a vacuum, a small blister (6 mm diameter) is formed on the skin; the tissue separates at the dermal–epidermal junction. The roof of the blister is then removed (“guillotined,” as it were) exposing a small area of dermis to which a drug solution can be directly applied. Feasibility, in vivo in man, was demonstrated using the antidiuretic peptide 1-deamino-8-D-arginine vasopressin (dDAVP) and stable, therapeutically active plasma levels were achieved rather quickly (117). The successful delivery of an oxytocin analog has also been shown (118). The authors claim that the dermal microcirculation remains intact and functional following creation of the erosion. Mild inflammation is observed and the erosion self-heals over time with, apparently, minimal scarring. However, practical applications of this approach, especially for chronic disease treatment, appears unlikely, and issues related to local infections will have to be addressed.

High-velocity particle delivery across the skin is the technology of a major drug delivery operation based in the UK and USA (PowderJect, Inc.) (119). Once a drug has been formulated as an appropriate and well-characterized powder, it is then introduced into a compact hand-held device in which a supersonic flow of gas accelerates the particles to a speed high enough that they can collide with the skin having enough energy to penetrate the outer layers and effect drug delivery. The depth and extent of delivery depends on the speed, diameter, and density of the drug particles. Again, insulin has been a peptide of choice for study by this method (120).

Finally, with the explosion of interest in micromachining and microfabrication, it is not surprising that drug delivery aficionados have turned their attention to the production of arrays of micron-sized microneedles capable of creating transport pathways across the SC without eliciting disagreeable perception on the part of the patient (121, 122). Various configurations and forms of these devices have been evolved, the majority of which involve extremely sharp tips and needle lengths on the order of 100 μm . At the time of writing, no specific publications detailing peptide/protein delivery using this technology have appeared.

Overall, then, the minimally invasive field is an active and imaginative one, of much perceived promise. However, it remains to be seen, as this technology matures and as it moves closer to real clinical testing against known effective methodologies, whether the current level of excitement (and investment) will be rewarded by the realization of successful and marketable products.

CONCLUSIONS

The relatively noninvasive nature of transdermal drug delivery, and the fact that this route can simultaneously avoid problems associated with presystemic metabolism and mimic (at least, to some extent) parenteral input profiles, are significant advantages. There have been, therefore, diverse attempts to exploit the skin for peptide and protein delivery. As we have noted before, transdermal administration, with or without one or more enhancement technologies, will always be limited to potent drugs and this accounts, once more, for the effort devoted to peptide and protein (i.e., typically very active substances) administration via this route.

Even the simplest structure-permeation relationships for percutaneous transport (no matter their limitations) indicate that the bigger a molecule, the poorer its diffusivity across the skin. Thus, larger molecules cannot be considered as transdermal candidates unless they are extremely potent. Vaccines are one such example and, given the skin's role as an immunological organ, represent a potentially very interesting opportunity for the transdermal route. For other peptides and proteins, at least to-date, an enhancement strategy appears to be obligatory in order that the skin's barrier function can be overcome.

The different approaches used have all yielded *some* effect, in that increased peptide/protein delivery has been

achieved. However, with the possible exception of iontophoresis, few of the various technologies employed have achieved an advanced state of maturity. Even in the case of iontophoresis, despite considerable activity and many publications in the literature, there are no peptide delivery systems on the immediate horizon (although there are products with "normal" drugs in the later steps of development). Typically, in the biotech era of the last 20 years, the newer technologies, including the "minimally invasive" methods (i.e., those about which we know the least and whose associated problems are poorly, or have yet to be, characterized!) are now attracting most attention and the highest level of investment.

It remains to be seen, therefore, whether the transdermal route will eventually yield a marketable delivery system for one or more peptides and/or proteins. For some of the enhancement technologies available, considerably more work needs to be done to establish that there is a distinct advantage over a needle and syringe (e.g., ultrasound, electroporation, and all "minimally invasive" methods); for iontophoresis, much of the groundwork has been done and the basic, mechanistic principles are becoming clearer—the challenge now is to identify the right peptide candidates and to initiate a serious development effort. Vaccine delivery appears to be an intriguing opportunity and of much interest; time will tell if the transdermal route will prove compatible with this important goal.

PHARMACEUTICAL EXCIPIENT TESTING—A REGULATORY AND PRECLINICAL PERSPECTIVE^a

Paul Baldrick

Regulatory Affairs-Pharmaceuticals, Covance Laboratories Ltd., Harrogate, England

INTRODUCTION

Pharmaceutical excipients are additives used in the formulation of pharmacologically active drugs and can be viewed as any ingredient of a medicinal product other than the active ingredient. Excipients include diluents, fillers and bulking agents, binders and adhesives, propellants, disintegrants, lubricants and glidants, colors, flavors, coating agents, polishing agents, fragrances, sweetening agents, polymers, and waxes. A review of the literature indicates approximately 1300 excipients used in the pharmaceutical industry. Chemical and manufacturing (quality) data can be found for many of these excipients in European, U.S., and Japanese pharmacopoeias (1–3) or in a range of other publications (4–6), but safety (preclinical) data are limited. General safety data can be found in some publications (5,7). Reference to excipients included in drug submissions is given in the FDA *Inactive Ingredients Guide* (8), the *National Formulary* (9), and the U.K. *ABPI Data Sheets* (10). It is assumed that reference to an excipient in these publications is a guarantee of acceptance by a regulatory body of the excipient in a new drug formulation. Although this is often the case, there may be gaps in the available data that may necessitate additional preclinical evaluation. The use of a novel excipient in a drug formulation necessitates preclinical testing and evaluation. This article addresses strategies for preclinical assessment of completely novel, essentially similar, and established excipients in view of current difficulties posed by the lack of a concerted international guideline relating directly to pharmaceutical excipients. In addition, the active role of excipients in producing adverse patient effects and in modulating active drug release is presented.

REGULATIONS AND GUIDELINES

From an international regulatory point of view, there is currently little help to address the question of registration of an excipient as a separate entity. Furthermore, there is no such thing as an approved excipient (11). In Europe, it is assumed that novel excipients need to be evaluated as new chemical entities (12–14). Established excipients are included in marketing authorization applications (MAAs) for new drugs, with the assumption that their presence and characterization in pharmacopoeias will not cause concern with European regulators. Information on excipients is expected in MAA applications (15). In the United States, the Food and Drug Administration (FDA) assesses and permits use of excipients as part of a new drug application (NDA). As in Europe, it is assumed that the use of an “approved” excipient ensures its acceptance in the new drug formulation. Thus, the FDA favors commercially established excipients (16). Interestingly, in the U.S. guideline relating to preclinical data for NDA submission, excipients are not mentioned (17). Although excipients per se are not mentioned in the Japanese guidelines (18), the situation with regard to such materials is similar to that in Europe and the United States. Under the new Japanese Ministry of Health and Welfare (JMHW) evaluation system (operational since 1997), the assessment of pharmaceutical products containing excipients with prior use in Japan is performed at the Pharmaceuticals and Medical Devices Evaluation Center (PMDE). Approval of a product that contains an excipient with no prior use in Japan has to be evaluated by the Subcommittee on Pharmaceutical Excipients of the Central Pharmaceutical Affairs Council (CPAC) concurrently with the approval process undertaken through the PMDE Center (19). Reasons for inclusion of the excipient; precedents of use; and quality, stability, and safety data are all needed.

The lack of international regulatory guidelines led to the formation of the International Pharmaceutical Excipients Council (IPEC) in 1991. This industry association, with European, U.S., and Japanese membership, has championed the international standardization of excipients,

^aUpdated from Pharmaceutical Excipient Testing—A Regulatory and Preclinical Perspective. In *Encyclopedia of Pharmaceutical Technology*; Swarbrick, J.; Boylan, J.C. (Eds.), 1st Ed., Marcel Dekker, Inc., New York, 2000, Vol. 19, 289–310.

the introduction of useful new excipients, and the development of safety evaluation guidelines. These guidelines, addressing all the primary routes of drug administration, have been published (16). These proposed safety guidelines has been given to the FDA by the IPEC, with a request for an evaluation procedure, independent of the NDA process, for new pharmaceutical excipients (20).

In Europe, the need for companies to fully consider the types of excipients in new drug formulations has been the focus of a guideline released recently by the European commission on drug label and package leaflet excipient information for all MAAs (14). This guideline indicates that all excipients must be listed on the drug label for parenteral, topical, inhalation, and ophthalmic products. For other medicinal products, only those excipients with a defined and recognized action of effect, as listed in the guidance document (over 40 materials are mentioned), need to be declared on the label. In drug package leaflets, all excipients must be included. European regulations and guidelines (12, 13, 21) also require that a full statement of the excipients used be given in the Summary of Product Characteristics (SPC) document for new drug formulations. In Japan, the identity and quantity of the inactive components must be indicated on package inserts and similar materials for medicines for oral use, injection, and applications on the skin and mucosal surfaces (22).

The situation is different in the United States, where labeling of inactive ingredients remains voluntary (23), although such labeling has been adopted by two major pharmaceutical industry trade associations (the Proprietary Association and the Pharmaceutical Manufacturers Association). It may be that companies are reluctant to give details on their products because the excipients will not have patent protection. Thus, full disclosure of excipients is still not a general practice and can lead to opposition (24). The FDA indicated, however, that inactive ingredients (that have the same meaning as excipients) that present an increased risk of toxic effects to neonates or other pediatric subgroups need to be noted in the contraindications, warning, or precautions section of labels on prescription drugs for humans (25).

In Europe, in the preclinical area stage, reference is made (but without any details) to the suitable demonstration of safety of any new propellant (26, 27). Vaccine guidelines group excipients (identified as inactive components including stabilizers) with adjuvants and preservatives as additives and indicate that safety appraisal is needed, again without details (28). A recent European regulatory guidance on the development of pharmaceuticals has stated that, "A new substance introduced as a constituent will be regarded in the same way as a new active ingredient H unless it is already approved for use in

food for orally administered products, or in cosmetics for topical administration. Additional data may still be required where an excipient is administered via an unconventional route, or in high doses" (29). However, although this wording may allow for some reduced data for commonly used nonpharmaceutical materials, it is unlikely that in the meantime in Europe, novel excipients will be treated as other than new chemical entities.

CATEGORIES

New (Novel) Recipients

A new excipient is a compound that has not been used previously or permitted for use in a pharmaceutical preparation (16). The need to develop an excipient as a new chemical entity, leading to expense and potential time delay (the excipient would be of low regulatory priority compared with active new drug formulations), has resulted in a reluctance in the pharmaceutical industry to introduce new materials. Indeed, it is likely that if there is doubt about the safety of an excipient, pharmaceutical manufacturers would rather reformulate than incur registration delays (11). Furthermore, despite the possibility that greater effectiveness of pharmaceutical products containing new excipients exists, a desire to avoid regulatory delays has resulted in a lack of research in this area (19). A review of the 12 most common excipients (water, magnesium stearate, starch, lactose, microcrystalline cellulose, stearic acid, sucrose, talc, silicon dioxide, gelatin, acacia, and dibasic calcium phosphate, respectively) in NDAs from 1964 to 1984 shows that six were being used in 1904, increasing to the majority of these materials by 1949 (30). A review of the most common excipients in U.K.-licensed medicines showed the following materials: water, magnesium stearate, povidone, sodium chloride, stearic acid, and dextrose (31). In 1992, Strattan reported that no truly new excipients have become available for general use in the past 50 years (32). The appearance of the cyclodextrins in the 1990s and the recent approval of the inhalation propellant hydrofluoroalkane (HFA) have only slightly changed this fact. The U.S. pharmaceutical companies have primarily used "grandfathering" for their new substances (using old "unapproved" drug formulations), thus preventing advancement in the use of excipients.

As noted above, the IPEC has proposed guidelines for the safety assessment of new excipients. It is hoped that implementation of these guidelines would expedite the review of a proposed new excipient by regulatory agencies

Table 1 Summary of excipient guideline^a

Tests	Routes of exposure for humans						
	Oral	Mucosal	Transdermal	Topical	Parenteral	Inhalation/intranasal	Ocular

(16). A summary of the IPEC guidelines is given in Table 1. This organization has defined a testing strategy for human exposure to single or limited dosing (less than 2 weeks), limited and repeated dosing (2–6 weeks), and long-term dosing (longer than 6 weeks). Different tests for oral, mucosal, transdermal, topical, parenteral, inhalation/intranasal, and ocular routes in humans are described. Common recommended toxicity studies for longer term use in humans include acute oral and dermal toxicity studies, eye and skin irritation studies, a skin sensitization study, genotoxicity and ADME studies, subacute and chronic studies, and reproduction studies. These guidelines are useful as a basis for the development of a new excipient, although they raise some questions. The basis for the guidance is that because of the defined inert nature of excipients, the safety assessment procedure should not be as complex or as extensive as that for an active drug. However, the program described is not dissimilar to the strategy used for an active drug. Furthermore, acute dermal, irritation, and skin sensitization studies are not routinely performed in new drug assessment unless there are specific issues or questions about the drug class. Finally, and most important, if a drug company was developing a drug with a completely new excipient in the formulation, it is possible to include the excipient alone as an extra dose group in the preclinical studies. These studies would presumably use the clinical formulation (containing the excipient). It is vital that kinetics studies identify any drug-excipient interaction. As for active drug, a sensitive analytical method is needed to measure levels of excipient (if possible) in plasma samples from toxicology studies. If the impurity profile of the new excipient causes concern, additional toxicological evaluation of each impurity has to be carried out as well. It is crucial to clarify the excipient impurity profile because even established pharmacopoeia-listed materials such as magnesium stearate can raise questions as to the safety and toxicity of its impurities (33).

In Japan, Uchiyama has recently published requirements for the safety evaluation of new excipients (19). These requirements include studies on acute, subacute, and chronic toxicity, mutagenicity, effects on reproduction, dependency, antigenicity, carcinogenicity, and local irritation (human patch test). The first five of these tests are mandatory. With the exception of the local irritation test, for which a domestic trial is required, non-Japanese data are acceptable for these studies. Even if a material has been used in a pharmaceutical product outside Japan, the material is treated as a new excipient if there has been no prior use in Japan, although relevant overseas data for the material are acceptable for regulatory submission. A material is treated as a new excipient

when the route of administration differs or the dose level exceeds that of prior use even after approval for the Japanese market (19).

Although not viewed as a typical excipient, the inhalation propellant HFA has been approved in both the United States and Europe in recent years. Because of concerns about ozone layer depletion defined in the Montreal protocol, the need for a replacement for chlorofluorocarbons (CFCs) in metered-dose inhalers (MDIs) used by patients with asthmas led to the development of two types of HFA (134a and 227) in Europe (34, 35). Both compounds underwent extensive preclinical testing in the early to mid-1990s. The change from established CFC-containing drugs to those with HFA requires toxicity-bridging studies. From a regulatory point of view, these studies can vary from 1 month to lifetime in duration. A recent U.S. publication has revealed a number of preclinical studies, including those for carcinogenicity, using hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs) as replacements for CFCs (36). The data show that the new HFA-134a and -227 excipients are as safe for use in humans as the CFCs they are replacing (37, 38). Using the example of HFA, it can be seen that even with government pressure to change a formulation, considerable time and effort are needed for the development of a new excipient.

Finally, with regard to the development of new materials for inhalation products, Wolff and Dorato suggest acute or short-term toxicology studies of a number of possible excipients in different formulations (34). This process will allow the narrowing to one or two acceptable possibilities that can then undergo more complete toxicological testing. The testing of new inhalation excipients is also addressed in a guidance from the FDA's Center for Drug Evaluation and Research (CDER) (39). A complete toxicological evaluation is recommended for a new excipient with unknown inhalation toxicology potential (such as a new propellant) alone as well as bridging studies in animals with the new complete formulation. Such studies are generally sufficient for regulatory approval.

Essentially New Excipients

Essentially new excipients can be thought of as substances resulting from a structural modification of an "approved" excipient, a recognized food additive, a structurally modified food additive, or a constituent of an over-the-counter (OTC) medicine. Food additives are similar to excipients in that they are used to impart specific functional characteristics and are usually added

in low levels (16). International organizations including the Joint Food and Agriculture Organisation (FAO) and the World Health Organization (WHO) Expert Committee (JECFA) have established safety standards such as an acceptable daily intake (ADI) or “generally recognized as safe” (GRAS) for a number of food additives, including materials that have applications as excipients. Safety evaluation of these additives involves a detailed risk-assessment process, with ADI calculations having factors such as 100-fold-above-animal data as safety margins.

Although not covered by any regulatory guidance, the safety of many food additives determined through JECFA evaluation and long-term human exposure allows for approval of these materials as new excipients in drug formulations without the need for extensive preclinical testing. Indeed, the FDA favors commercially established food additives and GRAS substances (16). However, limitations and possible significant financial investment exist because of the possibility of long waiting periods for approval and the fact that food additive data relate to oral administration and are of little use for nonoral products (11).

Additionally, problems may arise if the preclinical data on which the assessment is made are old and unreliable and raise specific toxicological concerns. Considering all these factors, it is probable that a robust expert review of available preclinical and human exposure data for a food additive may satisfy a regulatory body. As noted above, there is an indication in Europe that new pharmaceutical excipients already used in food for orally administered products or for topical cosmetics may not have to be considered new chemical entities, and therefore full evaluation may be bypassed (29).

Other problems may arise if the level of the food additive to be used as a proposed new excipient is higher than the ADI value or if a food additive or an established excipient are structurally (albeit simply) modified. The new material may have a different or more toxic profile. There are no easy solutions to these

situations for pharmaceutical companies. The regulatory answer will be that each material is assessed on a case-by-case basis. However, some form of preclinical testing will probably be required, and a possible minimal program is given in Fig. 1. In this program, an Ames study determines that the new excipient has no genotoxicity potential, and a single-dose toxicity study shows that there are no adverse effects after administration of the material at the limit (high) dose generally used in the pharmaceutical industry. An investigative mass, balance, whole-body autoradiography study provides information on absorption, distribution, metabolism, and excretion. This study also involves an investigation of suitable labeling of the material. An *in vitro* metabolism study (e.g., in rat versus human hepatocytes) may also be useful for modified food additives and excipients to compare the break-down process and to show possible differences between rat and human in these processes.

A 1-month toxicity study will establish whether the limit dose is causing any form of high-dose toxicity or metabolic overload. It may be useful to include toxicokinetic satellite animals in this study to demonstrate what level of exposure to the excipient occurs in the blood. Favorable findings from these studies can be presented to the regulatory bodies and advice sought as to whether additional testing is recommended. As with other preclinical studies in drug development, all these investigations should be performed according to good laboratory practice (GLP).

In the United States, OTC products do not need regulatory approval of submission of an NDA. Thus, if an excipient has a record of safe use in an OTC medicine, the FDA may accept the material, provided the product manufacturer can demonstrate evidence that the excipient is safe to use (11). However, this manner of approval is not guaranteed to be successful and may not be useful for nonoral administration routes.

In Japan, all these pathways to reduce ease the burden of introducing new excipients are more complex. If not already approved as a pharmaceutical excipient in Japan, food additives for oral administration or cosmetic substances for external application in drug formulations requires that they be treated as new excipients (19). For excipients already used in orally or intravenously administered products, a change to an externally applied product necessitates additional safety testing. Studies include acute and subacute toxicity (including adsorption through the skin) and local irritation investigations (19).

Many excipients used by the pharmaceutical industry in the last 15 years in sugar-free medical preparations

Fig. 1 Minimal preclinical testing strategy for an essentially new excipient.

probably come under the category of essentially new excipients. Pressure for their introduction has been encouraged by the definite relationship between the dietary consumption of sucrose and the incidence of dental caries (40, 41). These materials include intense sweeteners such as saccharin and cyclamate plus bulk sweeteners such as the polyols sorbitol, xylitol, and lactitol. These materials are all either approved for food use or have pharmacopoeia monographs in existence or in draft (42). Literature reviews show number of preclinical safety studies for these excipients. Many of these studies are related to specific toxicological concerns such as bladder tumor formation with saccharin use and adrenal glands and testes proliferation with polyol use (Table 2).

The cyclodextrins (CDs) fall into the categories of new and essentially new excipients. CDs are enzymatically modified starches with many favorable properties as excipients. The use of CDs in food products in the late 1970s and 1980s, together with extensive preclinical testing, has resulted in the inclusion of these materials in marketed drugs (32, 62). Various companies now market forms of CDs as safe and efficient delivery systems for active drugs.

Established (“Approved”) Excipients

The presence of well known established excipients in a new drug formulation does not necessarily mean that regulatory authorities question will not their inclusion. However, issues can be avoided if the excipient is clearly characterized in the quality section of the documentation and addressed sufficiently in the preclinical section. The preclinical assessment can take the form of an expert review of available safety data that defines safety margins between values reported in the literature and the level(s) used in the new drug formulation. This process is becoming easier for toxicologists as more data on established excipients become available through published literature reviews and/or publication of in-house studies. Examples include lactose (58), povidone or polyvinylpyrrolidone (PVP) (50, 63), saccharin (64), polyethylene glycols (PEGs) (65), HFA-134a (66), and vaccine adjuvants/excipients (67). Similarly, the establishment of global standardized monographs in major pharmacopoeias is helpful. However, it is surprising how little useful toxicology data are available for many well known materials such as maltodextrin, peppermint oil, and menthol.

Problems can arise when the currently available published data suggest that there may be potential toxicity concerns, especially when an excipient approved for one dose route is applied to another route with a different systemic exposure and target site. Scientific discussions of the data on the relevance of animal findings to humans, together with the establishment of safety margins, are necessary. The absence of toxicity findings in the new drug preclinical program that includes the excipient can also be used in these discussions. Examples of established excipients with reported toxicological concerns and the relevance of these findings to humans are given in Table 2. Another potential issue for discussion arises if the level of excipient in the new drug formulation exceeds that already known to the regulatory agency for prior use.

A less important but interesting point is that many of the established and pharmacopoeia-listed excipients are not accompanied by strict standardized assay methods. In this situation, a “new” assay needs to be established by the company with the new drug formulation for characterization and/or plasma measurement of the excipient.

The discussion above indicates that little or no extra preclinical studies are required for well known excipients. From an unofficial FDA regulatory perspective, this view is supported for inhalation excipients by De George et al. (39), who state that no additional toxicology information is generally needed for qualitative or quantitative changes of well characterized, nontoxic excipients used in approved inhalation drug products. A case-by-case assessment, however, will be used for reformulations because excipient toxicity may change. In addition, for excipients with previous use in humans but limited inhalation toxicity information, evaluation of inhalation toxic potential of the excipient after repeated dosing is recommended.

ADVERSE EFFECTS OF EXCIPIENTS

By traditional definition, excipients should be inert and display no pharmacological activity. However, a number of clinically relevant adverse reactions are known for various established excipients, albeit of low occurrence and uncommon compared with the overall prevalence of adverse drug reactions. This area is covered extensively in the literature (e.g., 7, 14, 23, 40, 68–71). Some examples are given in Table 3. Groups susceptible to excipient toxicity include low-birth-weight infants (particularly during the first 2 weeks of life) and patients

Table 2 Toxicological issues with various excipients

Excipient	Toxicological finding	Relevance to humans	Reference
Lactose and polyols	Adrenal medullary proliferative changes/tumors in rats	Considered to be rat-specific and caused by altered calcium homeostasis attributable to high dose levels given and not relevant to humans	43–45
Lactose and polyols	Hyperplastic/neoplastic changes in rat testes	See above	46
Saccharin	Proliferative changes in male rat bladder epithelium	Considered to be species-specific with large doses used. Mechanism of action may involve urinary proteins not normally found in humans	23, 40, 47–49
PVP	Accumulation in the reticuloendothelial system in rodents, with the occurrence of “foam cells”	Toxicological significance is unclear from the literature, but findings may be related to high-dose regimens used. No adverse effects from long-term storage in humans. There is also over 50 years of safe use for PVP in humans	50–52
Menthol	Limited sensitization reaction in guinea pigs	Toxicological significance is not clear from the literature, although very infrequent human allergy reactions are reported in the presence of menthol (8)	53
Limonene	Hyaline droplet formation in male rat kidney	Considered to be male rat-specific and related to the presence/accumulation of alpha 2 μ -globulin	54–56
Talc	Lung tumors in female rats	Related to high dose level and resulting chronic toxicity	57
Talc	Adrenal gland neoplasms (pheochromocytomas) in rats	Review of data indicates that tumors were not treatment-related	57
Maltodextrin	Minimal reversible laryngeal irritation (squamous metaplasia) with 4% maltodextrin in chronic rat inhalation study	Considered to be a background finding of no consequence to humans. May be related to the presence of peppermint oil (1%) in dosing preparation. ^{a,b} Local irritation of the mouth and oesophagus can occur in patients taking peppermint oil preparations (7, 10)	Personal observation
CFCs	Cardiac arrhythmias, notably in the dog	Relatively good safety margins and long/wide use of CFC propellants in MDIs has shown these compounds to be safe	34

^a Minimal laryngeal squamous metaplasia has also been reported in a chronic rat study with lactose (58) and may be related to a physiological adaptive response attributable to the inhalation of particulate dust at high levels over long periods. Certain histological changes in the respiratory epithelium have been defined as adaptive and not toxic (59, 60).

^b Peppermint oil contains a large percentage of menthol (30–55%) (1). Any question that the laryngeal irritation may be related to the presence of menthol within peppermint oil is doubtful because a recent chronic rat inhalation study has shown that 5000 ppm of menthol had no substantial effect on the histopathological changes in the respiratory tract normally associated with inhalation of mainstream cigarette smoke (61).

Table 3 Adverse effects encountered with various pharmaceutical excipients

Excipient (purpose)	Major adverse event(s)	Reference
Benzalkonium chloride (bacterial preservative)	Irritant known to discolor soft contact lens; rare hypersensitivity, bronchoconstriction	7, 14, 23
CFCs (propellant)	Bronchospasm	23
Aspartame (artificial sweetener)	Headache, various neuropsychiatric disorders, seizures, rare hypersensitivity reactions. Contraindicated for patients with phenylketonuria	7, 23, 40, 70
Saccharin (artificial sweetener)	Rare hypersensitivity, photosensitivity (with cross-sensitivity in patients with sulfonamide allergy)	7, 23, 40, 70
Benzyl alcohol (preservative)	Rare hypersensitivity reactions including contact dermatitis. Contraindicated for infants and young children because of high dose level toxicity	7, 14, 23, 70
Lactose (filler/bulking agent)	Contraindicated for patients with lactose insufficiency (diarrhea, abdominal pain)	14, 58
Propylene glycol (solubilizer)	CNS toxicity, hyperosmolality, lactic acidosis, hypersensitivity including contact dermatitis	7, 23, 70
Benzoic acid (preservative)	Irritant; may have role in asthma, urticaria, anaphylaxis, vasculitis	7, 14, 70
Ethanol (vehicle)	Irritation/dry skin. Contraindicated at high dose levels with liver disease, epilepsy, alcoholism, pregnant women, children	14
Polyols (artificial sweeteners)	Diarrhea	14, 58
Glycerol (vehicle)	Headache, stomach upset, diarrhea, increased serum osmolality, cardiac arrhythmias	7, 14
Sodium and potassium (supplement)	Adverse in cases of low sodium/potassium diet, stomach upset, diarrhea. Phlebitis and injection pain with potassium	7, 14, 23, 40, 70
Sulphites (antioxidants)	Allergic hypereactions, e.g., anaphylaxis, bronchospasm, gastrointestinal irritation/upset	7, 70
Gums, e.g., arabic, tragacanth (emulsifying agents)	Rare hypersensitivity reactions	7, 14, 70
Cremophor EL–Polyoxyethylated castor oil (solvent)	Anaphylactic reactions, nausea, vomiting, colic, hyperlipidaemias	7, 23, 70
Azo dyes e.g., tartrazine (dyes)	Anaphylactoid reaction. Contraindicated for aspirin-intolerant individuals	7, 70
Chlorobutanol (preservative)	Anaphylactic shock/hypersensitivity reactions, CNS toxicity	7, 14, 70
Formaldehyde (preservative)	Allergic reactions, stomach upset, diarrhea, irritant, role in asthma	7, 70
Aluminium hydroxide (adjuvant/adsorbant)	Aluminium allergy, skin nodules	7
Methylcellulose (stabilizer/suspending agent)	Intestinal upset	7
Hydroxyethylcellulose (stabilizer/suspending agent)	Ocular irritation	14, 40
Gluten/wheat starches (binders)	Intolerance for patients with coliac disease	

with asthma (69). It is interesting that, as for many adverse effects, most of the reported excipient-related findings in patients were not or could not be predicted by the preclinical data.

In Europe, it is now a requirement to include adverse excipient effects in the product leaflet in a consumer-friendly manner (14); information on ingredient content is also required in Japan (22). The fact that the labeling of inactive ingredients remains voluntary in the United States means that excipient-related adverse reactions will continue to be reported. Wong (24) highlights a worst-case scenario by showing that a drug can be marketed in various formulated dosage forms such as tablets, injections, and oral solutions, with each of these forms containing a different set of excipients that are not disclosed on the package label. Because the choice of excipients for any pharmaceutical preparation is decided by each company, different manufacturers producing the same drug may use different excipients in different proportions. Another potential issue is the quality of the excipients used in the drug formulation. Inferior grades of excipients may seriously jeopardize the quality and thus the potential safety and efficacy of the final product (24). Fortunately, standardization of the quality of excipients in pharmacopoeias reduces the significance of efficacy as an issue, although the example of the use of counterfeit excipients resulting in 90 pediatric fatalities in Haiti in the mid-1990s should not be forgotten (71).

Chowhan (33) points out the increasing awareness of excipient manufacturers and users of the importance and consequences of process changes. From a medical perspective for drugs with technically inert ingredients that are not necessarily pharmacologically inactive, full information is needed to facilitate the assessment and treatment of patient symptoms. Most excipient-related toxicity is preventable when the formulation is known (69,72). However, difficulty in obtaining such information from U.S. manufacturers continues to be a problem (73). Literature on the occurrence of well known excipients in pharmaceutical products is available as an aid to physicians in selecting preparations containing different excipients when an adverse reaction occurs (74, 75).

Overall, even in early drug development, a consideration of the excipient profile of the final product is important. If use of the established excipients is planned, an awareness of potential adverse effects in humans is necessary. Development should use pharmacopoeia-listed materials. For new excipients, this information is not available, and safety will be assessed in the preclinical evaluation. Extrapolation may only be possible if the new excipient is in the same class or is structurally similar to

established materials, but such a comparison would not necessarily be reliable.

DRUG-EXCIPIENT INTERACTIONS AND AN ACTIVE ROLE FOR EXCIPIENTS

That all excipients are neither truly inert nor inactive is shown by the fact that drug-excipient interactions can considerably affect the physiological availability of many drug products (76). By either accelerating or retarding the release of the active ingredients, excipients can affect the therapeutic performance of the drug by increased or reduced bioavailability (24,69). Indeed, relatively small variations in the physical properties of an excipient can produce a significant difference in the behavior of formulated products (5). In turn, the modified bioavailability may also result in adverse reactions. For modern drug-delivery systems, certain excipients can have a well defined function associated with the need to achieve a specific drug bioavailability profile or therapeutic effect (11). Liposomes (phospholipid-based vesicles) have been increasingly explored as novel drug-delivery systems, and there are examples of active excipient involvement, such as that with PVP- and PEG-liposomes, in development (77,78). Review of the literature shows a surge in interest in using excipients in sustained-release formulations in the 1990s. Various selective functional regions are identified, such as colonic targeting. Currently, many of these new formulations with an active role for the excipient have only been tested using in vitro pharmaceutical systems to establish release patterns, although the role of materials such as methylcellulose in tablet formulations for sustained release has been well established (5). It is beyond the scope of this article to review the progress of these developments, but Naidoo (79) has discussed the effect of excipients on controlled drug-release properties of dosage forms. Reports on controlled delivery of peptide drugs and vaccines using active excipient properties are also available (80,81). Such roles may reflect the definition of an excipient in the U.K. legislation on medicines as “any substance which does not contribute directly to the pharmacological action of the medicinal product otherwise than by regulation of the release of the active ingredients” (82).

Preclinical and clinical pharmacokinetics studies with a new drug indicate systemic exposure after administration of the therapeutic dose formulation. Thus, even if there is an interaction from an established or new

excipient, adequate safety evaluation can be assessed. However, it would be useful to demonstrate to a regulator that possible interference of the active drug by the rest of the formulation had been considered. If an excipient is added to the new drug form for an active role, the proposed mechanism of action will need to be discussed carefully.

OVERALL SUMMARY AND CONCLUSION

Pharmaceutical excipients have a vital role in drug formulations, a role that has tended to be neglected as evidenced by the lack of mechanisms to assess excipient safety outside a new drug application process. Currently, it is assumed that an excipient is “approved” when the new drug formulation of which it is a constituent receives regulatory acceptance. The existing system works for well known excipients that are listed in international pharmacopoeias and for which there are published safety data. However, drug companies are faced with a lack of information on the testing needed for completely or essentially new excipients (the latter category comprising recognized food additives, structurally altered approved excipients or food additives, or constituents of OTC medicines). Existing regulations and guidelines indicate that new excipients be treated as new chemical entities and therefore, by inference, undergo full toxicological evaluation. Other drug requirements in Europe and Japan require that information on excipients appear in patient literature, although there is no similar legal requirement in the United States.

For new (novel) excipients, drug companies need to carefully assess the benefits of using the new substance in consideration of the extra workload, costs, and possible regulatory delays or rejection. However, now that an active role for excipients is recognized in the form of sustained-release or drug-delivery systems, there is more need for companies to use new excipients. The replacement of CFCs with HFAs in inhalation therapy, although driven by necessary government demands, still involved extensive preclinical evaluation of the new excipient propellants and the usual regulatory approval times. Old CFC formulations with either HFA-134a or -227 as the new excipient are still being submitted and/or are under regulatory review and need to include bridging toxicity studies. The change from CFC has also meant modifications in MDI structure that, in turn, can result in the need for other formulation changes (and additional excipients). The publication of

the IPEC recommendations for safety evaluation of new excipients is helpful, although there is still no official response from the FDA. The suggested evaluation is not dissimilar to the full preclinical program necessary for a new chemical entity. If a drug company decides to introduce a new excipient, extensive preclinical data are probably necessary. However, if preliminary investigations, such as those given in Fig. 1, show that the material is safe at high dose levels, the excipient can enter the full drug development program as part of the formulation and/or in the form of an extra dose group. Expert evaluation of the data should identify any potential problems.

The situation for developing essentially new excipients is different inasmuch as some data on the material or a related material are available. Provided that these data are expertly evaluated and/or supported by some preliminary studies (as given in Fig. 1), along with the usual new drug studies, regulators should not raise disapproval. Each excipient, however, will be assessed on a case-by-case basis, with issues such as toxicological findings in the “old” data and duration of use of the excipient carefully assessed. As with new excipients, the increased workload and costs, along with regulatory approval time, will need to be considered. The cyclodextrins have entered pharmaceutical use by means of being present in food products. However, this process has taken many years and has involved extensive preclinical testing. Other materials such as saccharin have been established from food use, but they have had to undergo severe regulatory challenge over whether preclinical findings of bladder tumors are relevant in human use.

Established excipients pose some issues for regulatory consideration. Such issues include the use of a well known excipient by an “unapproved” route, for example, inhalation of a material that has been used in oral formulations. In these cases, some preliminary toxicity studies may be necessary. Additionally, a well designed scientific review of safety data on the excipient will be necessary, with old findings fully evaluated.

The acceptance that excipients are neither inert nor inactive substance and may affect drug bioavailability and cause adverse reactions (commonly hypersensitivity) means that even more consideration of these materials is needed when formulating new drugs. With these facts in mind, regulators will expend greater efforts to examine the ingredients in drug formulations. Furthermore, because there is no international requirement to provide details of drug formulations to health professionals (notably in the United States), adverse reactions will continue to be reported, putting extra pressure both on drug companies and

on regulators. Overall, the lack of regulatory guidance for excipient development leads to confusion for drug companies. In view of international agreement in other areas of drug development, an excipient-testing strategy would be an excellent topic for International Conference on Harmonization (ICH) consideration. Furthermore, with more standardization of pharmacopoeia materials, it may be possible to have excipients reviewed by a committee of an international pharmacopoeia. Safety data would be assessed by elected experts and published. Hopefully, these data would be acceptable to international regulatory bodies.

PHARMACEUTICAL QUALITY ASSURANCE MICROBIOLOGY

Anthony M. Cundell

Wyeth-Ayerst Pharmaceuticals, Pearl River, New York, U.S.A.

INTRODUCTION

The pharmaceutical microbiologist has an important role in product development, manufacturing process development, ensuring control of microorganisms in the manufacturing environment and routine raw material, inprocess material, and product testing. The involvement of experienced microbiologists in each stage of the product life cycle is important to maintain product quality. Typically, microbiologists are involved in formulation, manufacturing process development, and specification-setting decisions that can prevent microbial contamination of pharmaceutical products. In this chapter, the appropriate level of involvement of microbiologists in establishing the quality, purity, efficacy, and safety of pharmaceutical and over-the-counter drug products is discussed, and areas of future challenge to the pharmaceutical microbiologist are explored.

A review of the regulations governing the pharmaceutical industry outlines some of the formal responsibilities of the microbiologist. The U.S. Federal Regulations that govern the pharmaceutical industry are called Current Good Manufacturing Practices (cGMPs). The U.S. Federal Food and Drug Administration (FDA) was mandated by the 1962 New Drug Amendments to the U.S. Federal Food, Drug, and Cosmetics Act to promulgate regulations that had the force of law to ensure that drug manufacturers maintain the safety, identity, strength, quality, and purity of their products. These official regulations were published in the Federal Register, September 29, 1978, as 21 C.F.R. Parts 211 through 226 (1) as they pertain to drugs. The regulations are considered minimum requirements, and failure to comply with any part of the regulations during the manufacture, processing, packaging, or holding of a drug renders that product to be adulterated under section 501(a) (2) (B) of the Federal Food, Drug, and Cosmetics Act. The drug product as well as the persons who are responsible for the failure to comply with the regulations may be subject to regulatory action.

Sections of the cGMPs most pertinent to the pharmaceutical microbiologist include Subpart B Organization and Personnel: 211.22 Responsibilities of the

Quality Control Unit and 211.25 Personnel Qualifications; 211.113 Control of Microbiological Contamination; and Subpart I Laboratory Controls: 211.167 Special Testing.

The cGMP regulations require that a pharmaceutical manufacturer have an independent quality control unit responsible for approval or rejection of all components, drug product containers, closures, in-process materials, packaging materials, labels and drug products, review of production records for possible error, and investigation of manufacturing deviations. The quality control unit also reviews and approves all specifications and procedures impacting on the products and leads the investigation of manufacturing deviations and product failures.

The quality control unit must have access to an adequate testing laboratory to aid in the approval of the materials under its control. One of these laboratory facilities would be suitably equipped and staffed to conduct microbiological testing. The quality control unit need not manage the microbiology laboratory. The laboratory could be run by quality control, research and development, even manufacturing or could be a contract testing laboratory, provided it meets cGMP requirements and is responsive to the needs of the quality control unit. Although not a regulatory requirement, it is industry practice to use the audit process as a tool to ensure that the microbiology laboratory meets all regulatory requirements and internal company policies.

The 211.25 Personnel Qualifications requirement is that all persons engaged in all phases of pharmaceutical manufacture have the education, training, and experience to enable them to do their job and have a working knowledge of the cGMP regulations that applies equally to laboratory personnel. For example, bench microbiologists should have a bachelor of microbiology or allied life sciences degree and be adequately trained in the laboratory procedures and testing documentation conducted in the microbiology laboratory. They need to be assigned responsibilities in keeping with their level of skill and experience. Microbiologists with supervisory or managerial responsibilities need training in supervisory skills, scheduling, budgeting, laboratory investigations, technical report writing, pharmaceutical products, and the manufacturing processes. They need to understand the requirements of the quality control unit and ensure that

the unit is supplied with quality test results in a timely and cost-effective manner. Since the pressures to manufacture, test, and release products in a timely manner can be considerable, they need to work well under pressure and enjoy team work.

The educational background of bench microbiologists, supervisors, and managers is now even more important, given, the current transition from classic to nucleic acid-based testing methods.

The demands of microbiological testing require that the core educational background of the staff, supervisors, and managers be in microbiology. Training and experience in aseptic techniques are necessary. According to the author, the skill sets of chemists, pharmacists, and even biologists do not allow them to readily act effectively as microbiologists without extensive training. Course work invaluable to the pharmaceutical microbiologist includes:

- Isolation, enumeration, and identification of bacteria and fungi;
- Pathogenic microbiology;
- Microbial physiology and biochemistry;
- Introductory chemistry including organic, inorganic, and physical chemistry and quantitative analysis;
- Introductory physics;
- Introductory mathematics;
- Introductory pharmaceutical manufacturing;
- Introductory statistics and probability; and
- Written and oral expression with emphasis on technical report writing.

According to 211.113, Control of Microbiological Contamination, pharmaceutical manufacturers need written procedures describing the systems designed to prevent objectionable microorganisms in both nonsterile and sterile drug products. All sterilization processes used to manufacture parenteral drugs need to be validated.

There needs to be a laboratory test for each batch of drug product to determine that the product conforms to specification, including the identity and strength of each active ingredient, before release. Where sterility and/or pyrogen testing are conducted on specific batches of short-lived radiopharmaceuticals, such batches may be released before completion of this testing, provided such testing is completed as soon as possible. The 211.165 Testing and Release for Distribution regulation states that there be appropriate laboratory testing, as necessary, of each batch of drug product required to be free of objectionable microorganisms. This implies that each and every batch of product need not undergo microbial evaluation.

The pharmaceutical microbiologist in product development plays a major role in bring safe products to the market. Typically, the Research & Development (R&D)

microbiologist is found in the analytical development group. The role of the R&D microbiologist is to develop and validate the microbial tests that may be applied to the new pharmaceutical products to confirm that they are not contaminated with an excessive number of microorganisms or objectionable microorganisms that may infect patients or degrade the quality of the product during its shelf life.

These tests include compendial tests for microbial limits, sterility, bacterial endotoxins, and antimicrobial effectiveness.

These compendial tests need to be developed and qualified for each new products before the phase II clinical trials, which involve 100–200 subjects. Considering the large investment to bring a new pharmaceutical drug product to market, i.e., an estimated U.S. \$ 250–500 million, it is important not to jeopardize the future of a new product or the subjects in the clinical trial by administering a drug product that may be contaminated with objectionable microorganisms. However, for the results of microbial testing to have any meaning, the microbial test needs to be qualified as suitable for use with each product.

Many dosage forms have active pharmaceutical ingredients or contain preservative systems that may inhibit the recovery of any bioburden associated with the product. This inhibition may be overcome by inactivating the active ingredient or preservative system with neutralizing agents, dilution to overcome the inhibition, or a combination of both strategies. U.S. Pharmacopoeia chapters 51, Antimicrobial Effectiveness Test; 61 Microbial Limit Tests; and 71 Sterility Testing (2) contain specific instructions on how to qualify the test for use with specific pharmaceutical drug products and the microorganisms to use during this process.

A major concern for Pharmaceutical Operations, i.e., Materials Management, Manufacturing, and QA, is whether the R&D microbiologists develop microbial tests that meet the QA requirements of robustness, simplicity, and standard for ease of testing for the routine release testing of pharmaceutical products. Good communications between the two microbiology groups will ensure the smooth technology transfer of the most appropriate tests from R&D to QA.

During development of the manufacturing process, an experienced microbiologist should be consulted as to the potential for microbial contamination of the product. Issues may include the selection of appropriate pharmaceutical ingredients, the ability of the manufacturing steps to control microbial contamination, the validation of sterilization processes, the cleaning and sanitization of process equipment, the adequacy of the water system, the

holding times for intermediates, the training of personnel, and the design of the packaging.

CURRENT MICROBIOLOGICAL TESTING PRACTICES

The compendial microbial methods currently used for the routine testing of pharmaceutical products are generally conservative and may be used to referee disputes concerning the microbial contamination of pharmaceutical products. The USP is recognized as an official compendium by the U.S. Federal Food, Drug and Cosmetic (FDC) Act. USP standards are used to determine the identity, strength, quality, and purity of pharmaceutical articles. The “General Chapters” section of the USP includes requirements for tests and assays and is numbered from 1 to 999, whereas general information include chapters 1000 and above. Of particular interest to the pharmaceutical microbiologist are USP 24 Informational Chapters 1116, Microbiological Evaluation of Clean Rooms and other Controlled Environments; 1111 Microbiological Attributes of Pharmaceutical Articles; 1225, Validation of Compendial Methods; and 1231, Water for Pharmaceutical Purposes (3). Testing chapters pertinent to pharmaceutical microbiology and their JP and Ph. Eur. counterparts are as follows:

USP Chapter 51, Antimicrobial Effectiveness Test

Antimicrobial preservatives are substances added to multiuse nonsterile liquids, ointments, and creams and sterile injectable products to protect them from microbial contamination that may be introduced inadvertently during use of the product (postmanufacturing).

The test for antimicrobial effectiveness is used to demonstrate the effectiveness of any added antimicrobial preservative(s). Compendial references include USP 24 Chapter 51, Antimicrobial Effectiveness Test; JP XIII, General Information 3, Preservatives-Effectiveness Tests; and Ph. Eur. 3rd Ed., Biological Tests, 5.1.3., Efficacy of Antimicrobial Preservation.

USP Chapter 61, Microbial Limits Tests

The tests for microbial limits and recommendations for microbial quality criteria of raw materials, excipients, drug substances, and pharmaceutical products have been established in pharmacopoeial compendia for over 30 years. These tests are listed in USP 24, Chapter 61, Microbial Limits Tests; Ph. Eur. 3rd Ed., Biological Tests

2.6.12 and 2.6.13, Microbial Contamination of Products not Required to Comply with the Test for Sterility (Total Viable Count, Tests for Specified Micro-Organisms); and JP XIII 30, Microbial Limit Test.

USP Chapter 71, Sterility Test

The sterility test is applicable for determining whether drug substances, preparations, or other pharmacopeial articles are sterile as defined by the compendial method. A satisfactory result indicates only that no contaminating microorganisms have been found in the sample examined according to the conditions of the test. Therefore, the result is a function of the efficiency of the adopted sampling plan. Compendial references to sterility testing include USP 24, Chapter 71, Sterility Tests; Ph. Eur. 3rd Ed., Biological Tests 2.6.1., Sterility; and JP XIII 45, Sterility Test.

General Informational Chapter 1116, Microbiological Evaluation of Clean Rooms and Other Controlled Environments

The microbiological monitoring of air, surfaces, and personnel in facilities used for sterile pharmaceutical manufacturing is discussed in the USP 24 Informational Chapter 1116, Microbiological Evaluation of Clean Rooms and Other Controlled Environments. The chapter also covers the design and implementation of a microbiological monitoring program and suggests monitoring frequencies and microbiological acceptance criteria.

USP Informational Chapter 1231, Water for Pharmaceutical Purposes

Types of water and methods and specifications for testing them are listed in USP Informational Chapter 1231, Water for Pharmaceutical Purposes. The USP also references Standard Methods for the Examination of Water and Waste Water (APHA), 19th Ed., for information on specific test methods (4).

Other Testing Methods

New microbial testing methods are being introduced in the marketplace based on advanced technologies. These new tests represent improvements in the timeliness and quality of testing.

The USP 24 General Notices states that alternative methods may be used to determine that products comply with the pharmacopeial standards for advantages in

accuracy, sensitivity, precision, selectivity, and adaptability to automation or computerized data reduction or for any other special circumstances. Such alternative or automated methods must be validated; however, when disputed, the compendial method is conclusive because it is the official or referee test. In addition, USP Chapter 61, Microbial Limit Tests, states that automated methods may be substituted, provided they are validated and give equivalent or better results, whereas USP Chapter 71, Sterility Tests, states that alternative procedures may be used to demonstrate that an article is sterile, provided the results obtained are at least of equivalent reliability.

It is not required to have prior FDA approval to use an alternate method to a compendial test. According to 21 CFR 314.70, "Supplements and Other Changes to an Approved Application," the addition or deletion of an alternate analytical method does not require prior approval and may be filed in the Annual Product Report. However, we would need to document the equivalency of the alternate method to the regulatory or compendial test method and the validation report must be available for an FDA investigator to inspect at our manufacturing site. Where the test method is particularly novel it may be advisable to include the test in an NDA supplement so the FDA can review the new method and your company can get prior FDA approval before the new test method is implemented.

ORGANIZATION OF THE PHARMACEUTICAL QUALITY ASSURANCE MICROBIOLOGICAL TESTING LABORATORY

The microbiology manager has three major roles in the QA organization. They are: 1) establishing, staffing, and running the microbiological testing laboratory; 2) monitoring pharmaceutical ingredients, water for pharmaceutical purposes, the manufacturing environment, and finished products submitted to the laboratory to demonstrate control of microbial contamination of the pharmaceutical products manufacturing at the site; and 3) providing microbiological expertise to the QA organization to prevent microbial contamination.

The microbiology manager is responsible for the establishment of a suitably constructed and equipped laboratory; recruiting and retaining an appropriately educated, skilled, and experienced staff; and operating the laboratory in compliance with all company policies and cGMP regulations. The needs of business require that microbial testing be conducted in a timely manner so that products can be released to the market.

The microbiological monitoring program established at a pharmaceutical manufacturing site will depend on the range of products manufactured there. Typical microbiological monitoring programs for release testing and environmental monitoring for nonsterile and sterile product manufacturing sites are given in Table 1.

The general procedures to be followed when selecting a microbial testing strategy a Marketed Product Stability Program for pharmaceutical drug products based on cGMP and compendial requirements and commitments made in regulatory filings are tabulated.

These approaches are in general accord with C.F.R. 21, Parts 211.113 Control of Microbiological Contamination, Section (b); 211.137, Expiration dating; 211.167, Special Testing Requirements Section (a); U.S.P. 24 51, Antimicrobial Effectiveness Testing, 61, Microbial Limit Tests, 71, Sterility Tests, 85, Bacterial Endotoxin Tests, General Informational Chapter 1151, Pharmaceutical Dosage Forms and the June, 1998, Draft FDA Stability Testing of Drug Substances and Drug Products guidance document (5). The tests that may be included in the program include: 1) antimicrobial effectiveness testing, 2) Microbial Limit Testing, 3) Sterility Testing, 4) Bacterial Endotoxin Testing, and 5) Container-closure Integrity Testing.

Table 2 outlines a possible testing policy.

Antimicrobial Effectiveness Testing

The following principles apply to preservative effectiveness testing in a pre- and postmarketed product stability program.

1. The selection of the preservative system for multiuse new products is the responsibility of the R&D formulation group. Typical shelf specifications are 80 to 120% LS. The appropriate preservative system for the particular formulation should be demonstrated to be effective by microbial challenge down to at least 75% and preferably to 50% of the target concentration. It is recommended that during development, the product be formulated with preservative concentrations of 100, 75, and 50% of the labeled amount and be subjected to Antimicrobial Effectiveness Testing to determine the lowest effective preservative concentration.
2. The release and shelf-life specifications are established based on both the premarketed stability data for the preservative system concentration and the Antimicrobial Effectiveness Test results.
3. If the study outlined in item 1 was not conducted during product development, it is recommended that QA and/or the Technical Services groups undertake a study

Table 1 Sample microbiological monitoring programs

Dosage form	Monitoring	Frequency
Tablets and capsules	Pharmaceutical ingredients	Periodic after history is established; rule accept on supplier certificate of analysis
	Purified water Manufacturing environment Products	Loop daily and taps weekly Quarterly Periodic after history is established owing to low water activities of tablets and capsules
Topicals, otics, vaginal and rectal products	Pharmaceutical ingredients	As above
	Purified water Manufacturing environment Products	Loop daily and taps weekly Weekly or monthly Routine for products with high water activity; periodic after history is established for product with low water activity
Nasal sprays and inhalants	Pharmaceutical ingredients	As above
	Purified water Manufacturing environment Products	Loop daily and taps weekly Daily or weekly Routine for products with high water activity; periodic after history is established for product with low water activity
Injectable products, ophthalmic products, and inhalation solutions	Pharmaceutical ingredients	As above
	Purified water Manufacturing environment Products	Loop and taps daily Every shift in critical aseptic processing areas Every batch with the exception of terminally sterilized products approved for parametric release

Table 2 Sample testing policy

Dosage form	Microbial test	Testing plan	Test intervals^a
Tablets, powder-, and liquid-filled capsules	Microbial Limit Test (TAMC and TCYMC only)	Test development, scale-up, and validation batches only	0, 6, 12, 24, and 36 months.
Topical liquids, ointment, and creams	Microbial Limit Test (TAMC and TCYMC only); USP Antimicrobial Effectiveness Test (AET) for multi use products	Aw <0.75 test development, scale-up and validation batches only; Aw >0.75 all batches on stability for Microbial Limit and first three batches for Antimicrobial Effectiveness (AE) ^b	0, 6, 12, 24, and 36 months; 0, middle of stability period and expiry
Vaginal creams and suppositories	Microbial Limit Test (TAMC and TCYMC only) and AET	As above	0, 6, 12, 24, and 36 months
Rectal creams and suppositories	As above	As above	0, 6, 12, 24, and 36 months
Nasal sprays	As above	As above	0, 6, 12, 24, and 36 months
Inhalation sprays and aerosols	As above	As above	0, 6, 12, 24, and 36 months
Ophthalmic ointments and solutions	Sterility Test, Container-Closure Integrity (CCI) and AET	Test all batches on stability with the exception of the first three batches for AE ^b	0, 12, 24, and 36 months
Injectables and Inhalation solutions	Sterility Test; CCI and AET; Bacterial Endotoxin Test	Test all batches on stability with the exception of the first three batches for AE ^b	0 only; 0, 12, 24, and 36 months; 0 and expiry only

^aTime intervals suggested in the 1998 Draft FDA Stability Guide. Add additional annual test intervals if the expiration dating exceeds 36 months.^bJustify using a stability-indicating preservative assay only at all time intervals as a substitute for the USP Antimicrobial Effectiveness Test by confirming preservative efficacy at 50, 75, and 100% of label claim.

to justify the current specifications and the elimination of routine Antimicrobial Effectiveness Testing in the Stability Program.

4. All preservative systems for both parenteral and nonsterile dosage forms should meet the 3 log reduction at 14 days for bacteria, i.e., USP category I requirements. EP/BP Antimicrobial Effectiveness Testing would be run only if requested by the Marketing Group.
5. Preservative effectiveness testing should be included at the 3-, 12-, 24- and 36-month intervals for pilot validation batches or of the first three commercial batches of a new product only.
6. With subsequent batches, chemical assays would be used only to confirm the preservative level, because the effectiveness during shelf life is being demonstrated. If the formulation is changed, the preservative effectiveness must be verified with at least one batch throughout the shelf life.
7. The choice of additional challenge organism used in formulation development will be determined by 1) the range of activity of the preservative system, i.e., if a preservative system has reduced activity against *Pseudomonas* spp., additional organisms from these genera or related genera could be added to the challenge organisms; 2) the organisms considered objectionable for that product and dosage form; and 3) the frequency of isolation of organisms from the manufacturing environmental and product monitoring.
8. Repeat challenges should be limited to the evaluation of preservative systems that cannot be improved because of formulation difficulties and limitation owing to the intended site of use and products that may be misused during multiple consumer use.

Microbial Limit Test

The following principles apply to microbial limit testing within a pre- and post marketed product stability program.

1. The inclusion of a routine Microbial Limit Test in a marketed product stability protocol will depend on the pharmaceutical dosage form. Typically, the test would be used for only nonsterile products, particularly oral liquids, nasal sprays; and topical liquids, lotions and creams that have a sufficient water activity to support the growth of microorganisms. In contrast, tablets, powder and liquid-filled capsules, topical ointments, vaginal and rectal suppositories, nonaqueous liquids, and inhalation aerosols with a water activity too low to allow for the product to support the growth of microorganisms would not be routinely tested.

2. To establish a Microbial Limit Testing history, all development, clinical, scale-up, and process validation batches of new nonsterile dosage forms would be tested to verify that the pharmaceutical ingredients, manufacturing process, and packaging do not contribute the bioburden of the product. After the testing history has been established, products with a water activity below 0.75 should not include Microbial Limit Testing in the stability protocol.

Sterility Testing

The following principles apply to sterility testing within a pre- and postmarketed product stability program.

1. All injectable and ophthalmic products with the exception of terminally sterilized product subject to parametric release should undergo Sterility Testing at release.
2. Because the sterility assurance of an injectable or ophthalmic product is established through media fill or sterilization validation for aseptically filled and terminally sterilized products, respectively, Sterility Testing has been included in past stability protocols as a measure of container-closure integrity of the product throughout its shelf life. If there is a continued need because of previous regulatory commitments to include Sterility Testing in a protocol, then testing at release and expiry is recommended.
3. Whenever possible, Container-Closure Integrity Testing should be substituted for Sterility Testing as recommended in the draft FDA Stability Guide.

Bacterial Endotoxin Test

The following principles apply to Endotoxin Testing in a pre- and postmarketed product stability program.

1. All injectable products should be tested for endotoxin at release.
2. Because, in the absence of bacterial growth in the product, the endotoxin level will not increase on storage during shelf life Bacterial Endotoxin Testing is not indicated in the stability protocol. If there is a continued need to include Endotoxin Testing in a protocol, then testing at release and at expiry is recommended

Container-Closure Integrity Test

The following principles apply to integrity testing a pre- and postmarketed product stability program.

1. The integrity of the container-closure system as a microbial barrier should be assessed using an appropriately sensitive and adequately validated Container-closure Integrity Test.
2. One of a number of physical Container-closure Integrity tests may be selected and validated against the Bacterial Liquid Immersion Test. The Physical Leak Test should be correlated to bacterial ingress.
3. The selection of the physical Container-closure Integrity Test method should be made after consideration of the container-closure type, the performance criteria, and the available validated test methods.
4. Test methods described in the literature include bubble, helium mass spectrometry, liquid trace (dye), head space analysis, vacuum/pressure decay, weight loss/gain, and high-voltage leak detection (6).
5. The number of samples tested should reflect the sampling requirements provided in the USP 71 Sterility Tests.
6. The testing should be performed annually and at expiry.

The third role of supplying microbiological expertise to the Manufacturing and Quality Assurance is important because depth of experience in microbiology may be lacking in these organizations in some companies.

Typically, the management of these organizations is trained in chemistry, engineering, business, or pharmacy. Microbiologists should assist management to exercise the best judgment on microbiological issues. Given that the ultimate objective is to prevent microbial contamination of pharmaceutical and OTC drug products, it is important that pharmaceutical microbiologists be knowledgeable in the areas of microbiological testing, infectious diseases, compendial changes, regulatory issues, product formulation, and manufacturing processes so they can give credible advice.

A common practice in microbiological testing is that pharmaceutical ingredients and products are tested without full consideration of their significance. Sometimes, all raw materials purchased and product manufactured are submitted to the microbiology laboratory and tested, or if materials for testing are selected, insufficient judgment is made with respect to where materials are tested, i.e., materials with a low risk of microbial contamination are tested whereas materials with a high risk are not tested. Testing should always reflect the risk of microbial contamination. An important managerial tool to rationalize the microbial testing is the reduced testing program. An important aspect of a reduced pharmaceutical ingredient monitoring program, after supplier audit and an evaluation of the equivalency

of results from the supplier's certificate of analysis and the manufacturing site microbiological testing laboratory, is an understanding of the potential risk of the microbial contamination of a pharmaceutical ingredient, manufacturing environment, or pharmaceutical product. The microbiologist needs to make a judgment based on the source of the ingredient, how it is processed, its water activity and testing history, and how it is used in formulations to determine whether periodic microbial monitoring to ensure that the testing laboratory confirms the microbial results reported on the supplier certificate of analysis is justified.

IMPLEMENTATION OF NEW MICROBIOLOGICAL TESTING METHODS

Opportunities exist to implement new microbiological testing methods as alternatives to the compendial methods to improve the quality of the test results and reduce the product-release cycle time. Selection of candidate test methods, proof of concept studies, assay development and validation, regulatory approval, and implementation of the new microbiological testing methods are major issues that need to be addressed to take advantage of the new technologies. These new methodologies offer significant improvements in terms of the speed, accuracy, precision, specificity, etc., with which testing can be performed.

The majority of testing performed today relies on century-old methods based on the recovery and growth of microorganisms using solid or liquid microbiological growth media. This is true in part because these methods can be very effective and have a long history of application. However, they are often limited by slow microbial growth rates, unintended selectivity for microorganisms that grow in nutrient-rich culture media, and the inherent variability of microorganisms in their response to culture methods. Despite the limitations of current methods, acceptance of new and potentially superior methods is often slow because of the understandable conservative tendency of microbiologists.

This may be in part attributable to a lack of clear guidance regarding the demonstration of their equivalence to existing methods acceptable to regulatory agencies and validation of the equipment associated with the new methods.

Considerable guidance can be found regarding the validation of chemical methods that is applicable to microbial testing. Examples include USP Chapter 1225, "Validation of Compendial Methods," and a recent

publication by the International Conference on Harmonization (ICH), "Validation of Analytical Methods." These publications provide very specific instructions regarding the demonstration of new analytical chemistry methods and their equivalence to existing methods.

When instrumentation is developed for existing microbiological methods to automate sample handling, result reading, or data management, it is not difficult to demonstrate the equivalency of the alternate method using guidelines developed for chemical assays because the test remains essentially the same. In a similar manner, when a new technology continues to rely on the measurement of microbial growth (e.g., impedance, ATP bioluminescence, or other metabolic changes in a microbial culture), equivalence can be readily demonstrated. However, when a new method is based on novel technology without direct ties to the existing method (e.g., microbial identification by rRNA amplification versus patterns of biochemical reactions, or counting fluorescent-labeled bacterial cells instead of colony-forming units on an agar plate), demonstration of equivalency may require a new application of the validation principles, although the method provides higher quality results. The principles that can be applied to the validation of new microbiological testing methods are found in the recently published PDA Technical Report (7).

For convenience, the technologies are divided into growth-based technologies, viability-based technologies, cellular component or artifact-based technologies, and nucleic acid-based technologies as shown in Table 3.

IMPLEMENTATION OF A RISK-BASED MICROBIOLOGICAL TESTING PROGRAM

A testing program to be both cost-effective and to control microbial contamination must reflect the potential risks of microbial contamination of pharmaceutical drug products. A knowledge of product formulation, manufacturing processes, packaging, and ability of product to support microbial growth can be applied to develop rational specifications and a monitoring program that reflects the potential risk to the consumer of each dosage form. This emphasis on potential risk will require that the pharmaceutical microbiologist most closely addresses products having a higher potential for microbial contamination to best serve the needs of pharmaceutical companies and end-user of products.

A recall is a removal or correction of a marketed product by the pharmaceutical manufacturer when that product violates the laws enforced by the FDA. Unlike the FDA's other methods for achieving compliance such as seizures and court-ordered injunctions, recalls are almost always voluntary. The FDA cannot order a company to recall a product, except in some cases involving infant formulas, biological products, and devices that present a serious health hazard. A class I recall occurs when there is a reasonable probability that the use of or exposure to a violative product will cause serious adverse health consequences or death. A class II recall occurs when use of or exposure to a violative

Table 3 Classification of new biological testing methods

Testing method	Example technologies
Growth-based technologies	ATP bioluminescence Impedance/conductivity Hydrophobic grid membrane filter methods
Viability-based technologies	Direct epifluorescent filter Microscopy membrane laser Scanning fluorescence cytometry Fluorescence flow cytometry
Cellular component or artifact-based technologies	GL chromatographic fatty acid profiles MALDI-TOF mass spectrometry Fluorescence antibody techniques Enzyme-linked immunosorbent assay <i>Limulus</i> amoebocyte lysate-endotoxin assay
Nucleic acid-based technologies	Nucleic acid probe Polymerase chain reaction–DNA amplification 16S rRNA sequencing techniques Automated riboprinting

Table 4 Summary of the nonsterile pharmaceutical and OTC products recalled, 1991–1998, by the FDA because of microbial contamination problems as to class of recall ($n = 46$)

Year	Recalls	Class I	Class II	Class III	% <i>Pseudomonads</i>
1998	7	2	3	2	57
1997	5	1	2	2	60
1996	4	1	2	1	75
1995	4	0	3	1	0
1994	8	1	4	3	38
1993	9	0	6	3	44
1992	6	1	5	0	33
1991	3	0	0	3	0
1991–98	46	6	25	15	38

(From Ref. 8.)

product may cause temporary or medically reversible adverse health consequences or in which the probability of serious adverse health consequences is remote. A class III recall occurs when use of or exposure to a violative product is not likely to cause adverse health consequences. When the center receives the Recall Report from the FDA district office, it evaluates the health hazard presented by the product and categorizes it as class I, II, or III. The classification is determined by an ad hoc Health Hazard Evaluation Committee made up of FDA scientists chosen for their expertise. Classification is done on a case-by-case basis, considering the potential consequences of a violation.

The average number of recalls per annum for microbial contamination of nonsterile pharmaceutical and OTC drug products is six (Table 4). The emphasis on waterborne Gram-negative bacteria of the species *Burkholderia* (*Pseudomonas*) *cepacia* (nine recalls), *P. putida* (three recalls), *P. aeruginosa* (three recalls), *Pseudomonas* spp. (two recalls), and *Ralstonia* (*P.*) *pickettii* (one recall) is notable and reflects the concern for bacteria capable of growth in liquid oral dosage forms that overwhelm the preservative system.

Analyses of the underlying probable cause of the microbial contamination of nonsterile products suggest to this researcher that they are the result of: 1) microbial contamination of water for pharmaceutical purposes, 2) the use of pharmaceutical ingredients with higher microbial counts, 3) failure of preservative systems to protect liquid products, 4) microbial contamination during the manufacturing process, or 5) improper use and/or storage of the products during shelf life.

The suitable water systems, the appropriate management of the equipment, and the appropriate monitoring programs were emphasized during past regulatory

inspections so that manufacturers have no excuse for using unsuitable ingredient water during the manufacture of products. In most cases, pharmaceutical ingredients of high microbial quality can be selected for pharmaceutical manufacturing. More emphasis must be placed on preservative systems during formulation development, especially on opportunities to optimize a preservative system by manipulating the pH, surfactant properties, and water activity of formulations to make them unsuitable for microbial growth. A comprehensive discussion of the application of water activity determination in product formulation and the development of microbial monitoring programs has appeared recently in the literature (9).

A greater appreciation of the ability of different manufacturing steps to affect the microbial content of a formulation by formulators, microbiologists, and manufacturing personnel would be helpful. Exposure of pharmaceutical products to high humidity during shelf life may increase the water activity of a liquid, ointment, cream, or tablet, allowing for the growth of microorganisms on the surface of the product. Thus suitable packaging and appropriate patient handling of the drug product are important.

FUTURE TRENDS IN THE MICROBIOLOGICAL TESTING LABORATORY

The four major trends in the pharmaceutical microbiological testing laboratory are: 1) the drive to introduce new microbiological testing technologies, 2) the organization of the laboratory based on work stations, 3) the use of computerized information management systems, and

4) the change of emphasis from testing to prevention of microbial contamination.

If the pioneering German bacteriologist Robert Koch visited a routine microbiological testing laboratory in the pharmaceutical, biotechnology, or medical device industry, he would recognize that most of our techniques were first developed or used in his laboratory during the last three decades of the 19th century.

These methods include the fixing and staining of bacterial cells on glass slides for microscopic examination and photomicroscopy; growth of colonies in solid media; streaking for isolation of pure cultures in solid media; the use of agar-agar as a support for microbiological media in Petri dishes; serial dilution and plating in solid media to enumerate the microbial population in water; monitoring bacteria in the air; the classification of bacteria by their cellular morphology and differential staining; sterilization of microbiological media by filtration or steam sterilization; disinfectant testing; and aerobic and anaerobic incubation. A major trend is under way in the pharmaceutical QA microbiological testing laboratory in which the classic microbiological cultural methods developed in the late 19th century will be replaced for routine testing by biochemical, fluorescent cytometric, and nucleic acid-based techniques. Although many companies have developed instruments to automate the running or miniaturizing of existing test methods, technological improvements are progressing rapidly, with new methods based on fluorescent laser detection and nucleic acid-based detection. The future of microbiological testing is in the commercialization of automated specific detection methods that will reduce our reliance on cultural methods. This should result in routine testing with significantly shorter test cycle times and higher quality results.

Organization of the microbiology laboratory is more and more frequently based on self-directed work teams, with the widespread use of workstations based on the newer testing technologies. The workstations will reflect the product mix manufactured by the pharmaceutical company. This will rationalize the deployment of lab personnel and the flow of materials and information through the laboratory. Common workstations include: 1) sample receipt and distribution, 2) water for pharmaceutical monitoring, 3) microbial limits of pharmaceutical ingredients and nonsterile products, 4) antimicrobial effectiveness testing, 5) microbial identification, 6) environmental monitoring, 7) growth promotion, 8) sterility testing, 9) microbial assay of antibiotics and vitamins, and 10) information management.

Each testing workstation manned by trained laboratory personnel who will rotate through the laboratory contain dedicated testing equipment interfaced to LIMS, media, reagents, and supplies, with accompanying SOPs, training documents, and calibration and preventative maintenance logs. Test specimens would be received, inspected, and entered into the information management system via keyboard or by bar code scanning and distributed to the appropriate workstation. The results would be generated at the workstations, and test results will be reviewed and transferred from the workstation into LIMS.

In conclusion, the important role of the microbiologists in the pharmaceutical industry must be reinforced. The need to involve experienced microbiologists in each stage of the product life cycle to maintain product quality, safety, and efficacy is highlighted in this chapter.

Pharmacokinetics: Effects of Food and Fasting

Rajesh Krishna

Bradford K. Jensen

Aventis Pharmaceuticals, Inc., Bridgewater, New Jersey, U.S.A.

INTRODUCTION

Patient compliance may be improved when drug administration is tied to meal timing and intake. However, depending on the drug, the composition and the size of the meal, and the time of food intake relative to dose administration, the pharmacokinetic properties of the drug may be altered. These perturbations in the pharmacokinetics of a drug as mediated by food may cause a wide range of effects including increased drug absorption, prolonged time to peak concentrations, increased variability in drug exposure, decreased drug absorption, or inhibition of metabolism and elimination processes. Many times, these changes may adversely influence the safety and efficacy of the drug substance or product and they are highly undesirable. For new chemical entities that have been approved for marketing, the label alerts the patient and the physician by including a statement under Dosage and Administration on the extent of alterations in peak concentrations (C_{\max}) and area under the plasma concentration vs. time curve (AUC), potential clinical significance and directions on time of dose administration relative to time of meal intake. The Food and Drug Administration (FDA) has issued a draft biopharmaceutics guidance for industry entitled "Food-Effect Bioavailability and Fed Bioequivalence Studies: Study Design, Data Analysis, and Labeling" in October 2001. However, a final guidance has not yet been issued to date.

A number of intrinsic and extrinsic factors influence the pharmacokinetics of a drug in both the fasted and the fed states. These include anatomical, pathological, and physiological factors as well as the physical and chemical properties of the drug, formulation, or excipients. Because of the inherent complexities in perturbations that food may cause in the pharmacokinetics, safety, and efficacy of a drug, food-effect assessments in early drug development are typically performed proactively by pharmaceutical companies to facilitate design of pivotal clinical efficacy studies and, eventually, the drug product label. This article will highlight the factors influencing the pharmacokinetics of the drug in the fasting and the fed conditions as well as the importance of performing food-effect studies in early drug development. This article will also provide a pharmaceutical industry perspective on the

models that are presently available to predict the presence and the extent of food-mediated alterations in absorption, metabolism, and clearance as they relate to a drug development program. Although food intake can affect the pharmacokinetics of a drug for a number of routes of administration, the emphasis of this article will be on drugs administered via the oral route of administration.

EFFECTS OF FOOD ON THE PHARMACOKINETICS OF A DRUG

Food has a myriad of effects on the pharmacokinetic behavior of a drug substance regardless of therapeutic class (Table 1). Key variables include the meal itself, the composition of the meal, the drug, the formulation, the concomitant medications, the time of day, and the disease pathology. Such differences are often as a result of altered physiological influences mediated by food. Examples of these physiological effects include the degree to which the gastric emptying rate is reduced, the variations in the degree to which digestive enzymes are secreted, the dynamics of an altered pH and the consequences for ionized drugs in the gastrointestinal (GI) tract, the biliary excretion, and the stimulation of hepatic and/or splanchnic blood flow. Other important influences include physical interaction between the elements of food and the drug itself, which can interfere with absorption of a drug or merely act as a barrier to absorption from gut mucosa. Fig. 1 is a representative illustration of how a plasma concentration vs. time profile appears for a drug given in the fasted state and its effects (increased or decreased absorption) in the presence of food. For a comprehensive review of the effects of food on the pharmacokinetic behavior of drugs, the reader is referred to authoritative reviews published by Welling, Fleisher et al., and Singh.^[1-5] The discussion below is primarily centered on how this knowledge can be integrated into rational drug development. Examples are drawn from case studies of drugs in drug development, the issues of identifying food effects early in the development, timing, design, and conduct of such studies as well as the issues and opportunities in this specific area of drug development.

Table 1 Partial list of drugs whose pharmacokinetics are influenced by intake of food

Abacavir
Adinazolam
5-Aminosalicylic acid
Atorvastatin

Venlafaxine
Zolmitriptan

HUMAN FOOD-EFFECT STUDIES AND AVAILABLE PHARMACOKINETIC METHODOLOGIES

The variation in the size and intake of food, the type of food, ethnicity, the caloric value, the fat content, the time gap between meals, and the intergastric volume can influence the physiological environment wherein the drug may find itself upon administration. All of these factors may result in alterations in the bioavailability of a given drug such as stimulation of biliary secretion and splanchnic blood flow, changes in GI pH, or delay in gastric emptying. In order to capture these perturbations in bioavailability, the FDA recommends a high-fat and high-calorie meal for testing the effect of a meal on drug pharmacokinetics.^[8] Historically, this meal has been considered a “worst case scenario” for a drug–food interaction study. For new chemical entities submitted for approval in the United States, well-controlled pharmacokinetic studies are performed using this “standard high-

fat meal” as the fed condition. One may argue that the above definition of standard high-fat meal is probably not representative of a standard breakfast in the United States or other parts of the world. Exceptions include vegetarian or vegan meals, low-fat/low-calorie meals for diabetics as recommended by the American Diabetic Association (ADA), and meals that are specific for each ethnic group. All of these differences compounded by genetic predisposition to pharmacokinetics may profoundly impact the pharmacokinetics of a drug and its prescribing habit. Nonetheless, keeping the type (or lack) of meal as a constant, one can elucidate the effect of other variables (formulation, time of meal intake relative to dose, etc.) on pharmacokinetics keeping in mind that the meal should be reflective of one that is used (recommended) during patient therapy.

There are two types of food-effect studies that are often performed in humans. These studies are designed to provide dosing recommendation with meals or to provide a mechanistic investigation on the effect of food on the pharmacokinetics of drugs. Examples of the former include studies done in conformity with the FDA guidance on food-effect studies or called “standard assessments.” Examples of the latter include exploratory mechanistic studies to investigate gastric emptying using tools, such as gamma-scintigraphy, or modulating gastric pH using ranitidine coadministration, with the aim to provide/elucidate underlying reasons for observed food effects.

Standard Food-Effect Assessments—Regulatory and Product-Labeling Considerations

The draft FDA guidance entitled “Food-Effect Bioavailability and Fed Bioequivalence Studies: Study Design, Data Analysis, and Labeling” provides sponsors with information on the design of appropriate studies to assess impact of food-mediated alterations in pharmacokinetics and to provide suitable dosing guidelines on drug product label.^[8] The guidance provides useful strategies for bio-waivers if the drug in question belongs to a particular Biopharmaceutics Classification System (BCS) category.^[6,7] For example, for highly soluble and highly permeable drugs (i.e., BCS Class I), food effects should be inconsequential (between test and reference products) due to the inherent properties of the drug. The premise is that the compound is minimally influenced by food as a result of pH- or site-independent absorption and lack of dissolution differences.

A suitable study design for definitively assessing the influence of food on the pharmacokinetics of a drug or drug product includes performing a single-dose, randomized, balanced, two-period, two-treatment (fed vs. fasted)

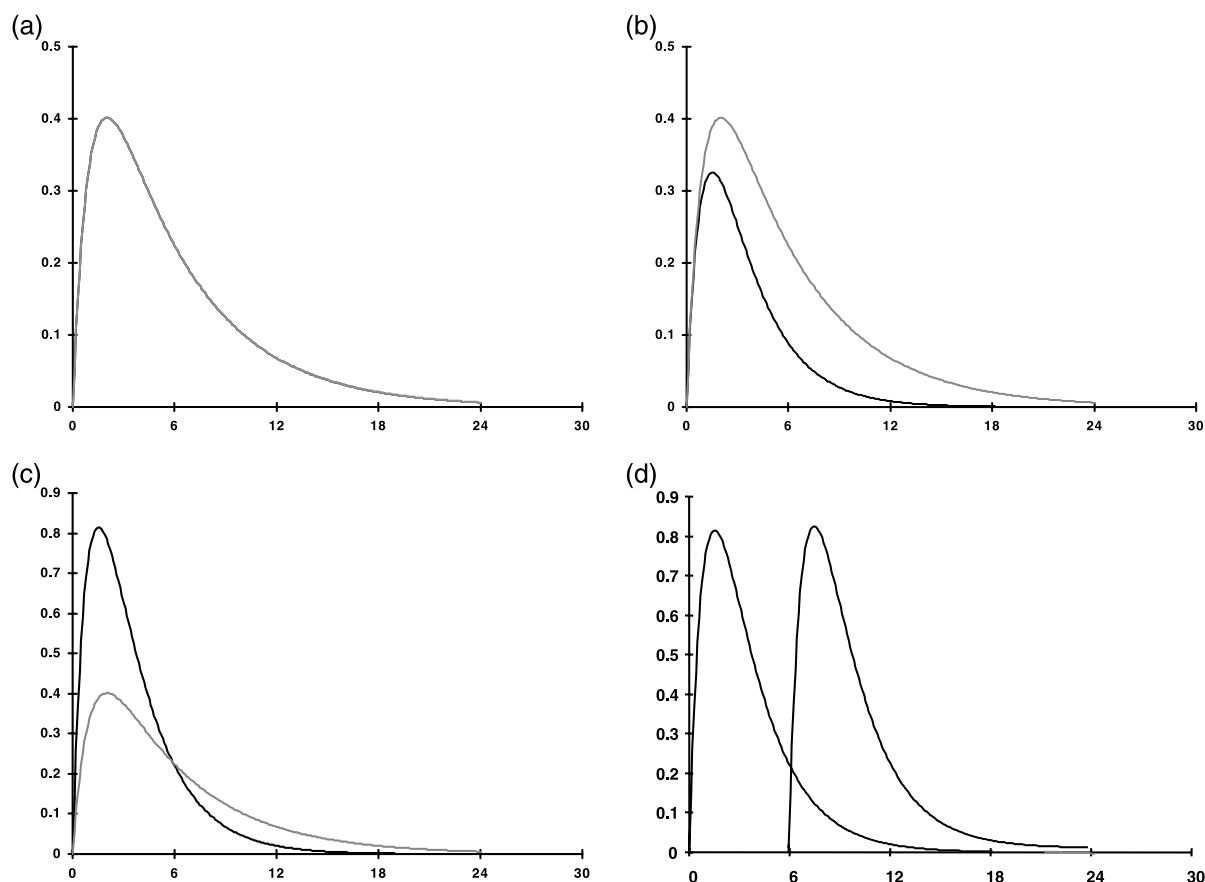

Fig. 1 a: Representative plasma concentration vs. time profile of a drug A after oral dosing in the fasted state. b: Food decreases exposure (C_{\max} and AUC) of drug A. c: Food increases exposure (C_{\max}) of drug A. d: Food delays exposure but does not decrease or increase exposure (C_{\max} or AUC) of drug A.

crossover study, with an adequate washout period between treatments. The number of subjects in the study should provide adequate statistical power for capturing small differences in exposure variables [peak concentrations (C_{\max}), T_{\max} , and area under the plasma concentration vs. time curve (AUC)]. The guidance also asks for using the highest strength of the formulation to be evaluated in such studies. For the fasting treatment, at least a 10-hr fast prior to dosing is recommended: “Following an overnight fast of at least 10 hours, subject should take the drug product. No food should be allowed for at least 4 hours post-dose. Water can be allowed at libitum after 2 hours. Scheduled standardized meals should be served throughout the remaining study period.” The issue is not the “number” of hours of predose fast time, but the stomach volume. If it contains < 50 mL (fasting state depends on the volume present in the upper region of the stomach), the stomach is in an interdigestive state. It is generally recommended to have a postdose fast time of about 4 h. For the fed treatment, the regulatory

guidance indicates a standard high-fat meal composed of two eggs fried in butter, two strips of bacon, two slices of toast with butter, 4 oz of hash brown potatoes, and 8 oz of whole milk. The caloric breakdown of this meal translates into approximately 150 cal from protein, 250 cal from carbohydrate, and 600 cal from fat. Standard pharmacokinetic calculations are performed using noncompartmental methods, e.g., C_{\max} , AUC, T_{\max} , etc. The guidance provides directions on how the data are applied to claim label attributes; for example, the degree to which 90% confidence intervals for the ratio of geometric means between fasted and fed legs are contained relative to the bounds of 80–125% for AUC or C_{\max} .^[8]

One issue that routinely arises is how to provide the FDA-recommended high-fat meal at non-U.S. investigative sites, where this meal is not readily accessible. Simple substitution of locally available food (e.g., sausage for bacon) that maintains the caloric breakdown of the FDA-recommended high-fat meal has been an acceptable approach.

A second type of study involves applying food as a covariate in population pharmacokinetic models.^[9–11] This is an emerging area of interest that is gaining regulatory concurrence. The advantages of using multilevel population pharmacokinetic models include the determination of the extent of both interindividual and intra-individual variability, the use of a limited sparse sampling approach, and the use of multiple covariates within a large Phase III trial setting. This strategy allows the simultaneous analysis of relevant covariate relationships (negative vs. positive correlation, proportional correlation, etc.) influencing the key pharmacokinetic parameters as a function of body surface area, age, weight, sex, hematological or biochemical indices, creatinine clearance, and, more importantly, any delays in drug absorption as mediated by food intake. Such analyses can be performed using tools, such as NONMEM, with standard conditional estimation methods (first order, first-order conditional estimate, or first-order conditional estimate with interaction, etc.). This allows for estimation of typical values for key pharmacokinetic parameters, V/F , CL/F , absorption rate constant, or lag time. Shepard et al. used a sequential approach with an indicator variable to assess the effect of food on the parameter of interest.^[11] Their model included $K_a = \theta_1(1 - Q) + \theta_2Q$, where Q was an indicator variable with a value of 0 (fasted) or 1 (fed), and θ_1 and θ_2 were the parameters of interest, with $K_a = \theta_1$ for fasted treatment and $K_a = \theta_2$ for fed treatment.

A number of recent examples in the literature describe the powerful use of population pharmacokinetic strategies to maximize information pertaining to food-effect behavior. These include a combination of noncompartmental and population pharmacokinetic analyses to answer a scientific question. For example, Zhou et al. used noncompartmental analysis to determine the extent of decrease in bioavailability of a drug mediated by food and then showed, using deconvolution and subsequent population pharmacokinetic analysis to assess the impact of meal timing on absorption, that the reduction in bioavailability under fed conditions was related to a reduction in the extent of absorption and not to a reduction in the rate of absorption.^[10] The use of the population pharmacokinetic approach in a multicenter trial in patients to assess food effect using sparse sampling and several categorical and continuous covariates is a more common application of this strategy. However, it is not clear that a population pharmacokinetic approach definitively addresses a food interaction without a traditional Phase I study.

Scintigraphic Assessments

The technique of gamma scintigraphy has been used to evaluate biopharmaceutical properties of drug substances

administered orally in the fed and the fasted states to evaluate food effects. Specifically, the procedure allows for studying GI transit of radiolabeled drug formulations in the fed state. With this method, one can understand the physiological processes by which the GI tract manages food and how the stomach empties meals of varying chemical composition. Such type of studies may also reveal the potential sites of absorption of an investigational product throughout the GI tract and how this is impacted in the fed state. This information is particularly useful when designing modified-release formulations. Technetium (^{99m}Tc) is a widely used nuclide in radiopharmaceuticals because of its optimal energy, short half-life, and small radiation dose needed. For a basic review on pharmacoscintigraphy tools available, the reader is referred to an excellent review by Wilding et al.^[12]

MODELS FOR ASSESSING IMPACT OF FOOD ON THE PHARMACOKINETICS OF A DRUG SUBSTANCE

In Vitro Models

Biorelevant dissolution models have been described in the literature as a means to predict food-effect behavior on the absorption of drugs.^[13–17] Reppas et al. have suggested several dissolution media that simulate fasted and fed conditions in the human body.^[14–17] They used milk (3.5% fat) and United States Pharmacopeia (USP)-simulated gastric fluid with and without pepsin as dissolution media representing the fed and the fasted states in the stomach, respectively. Dressman and Reppas have showed that such biorelevant media have distinct advantages over compendial media in the prediction of food effects for poorly water-soluble drugs.^[15] An example of how dissolution tests may be used to predict the in vivo effect of food on drug absorption is highlighted in Fig. 2 for a BCS class II (highly permeable, poorly water-soluble drug) drug, danazol. Fig. 2a shows the dissolution profile of danazol in different media, namely, water, simulated intestinal fluid (SIF), FaSSIF, and FeSSIF.^[17] FaSSIF represents the fasted state in small intestine and FeSSIF represents fed state in small intestine. From these dissolution tests, it is clear that there is enhanced dissolution in the simulated fed state relative to the simulated fasted condition. Not surprisingly, the extent of this in vitro increase is similar to the extent of increase in danazol exposure in human subjects observed in the fed state as shown in Fig. 2b.^[18] The mechanism of food effect is related to increased solubilization mediated by bile salts for this steroid drug.^[15] This strategy appears to be predictive of drugs that belong to

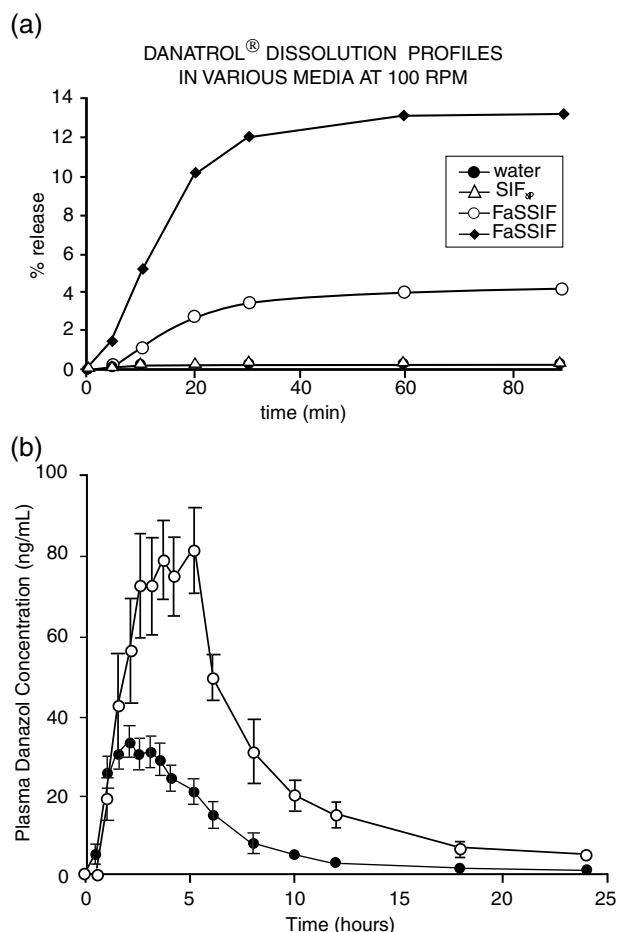

Fig. 2 a: In vitro dissolution profile for Danazol. (From Ref. [17].) b: In vivo plasma concentration vs. time profile for Danazol (closed circles represent fasted state and open circles represent fed state). (From Ref. [18], Sage Publications/Corwin Press Inc.)

the BCS Class II category and may not be generally applicable to drugs belonging to other categories.

In Vivo Models

A number of animal models have been used to describe the fasting and the fed pharmacokinetics of drugs with the aim of predicting human performance. These include mice, rats, rabbits, guinea pigs, dogs, pigs, monkeys, to name a common few. The discussion below will address the relative merits and demerits of rodents, dogs, and pigs as predictive models for humans. It should be kept in mind that animal models may be helpful in assessing large and overt food interactions in oral bioavailability. However, relatively small differences that may be ultimately important in human studies and therapeutics will probably not be detected.

Rodents

Rodents (mice, rats, guinea pigs) are generally not preferred as models for assessing food effects for various reasons, namely, differences in GI anatomy and physiology, difficulties in administering “human” food, and lack of implementing a crossover design assessment. Other potential caveats include differences in the pharmacokinetic and the metabolism behavior in rodents as compared to humans and nonhuman primates that may negate assessment in this species. Metabolic profiling of the investigational product in a panel of animal models will reveal the suitability of a particular species as a predictor of human pharmacokinetic behavior. Furthermore, the extent of serial sampling is also constrained in smaller rodents such as mice. However, rodents are one of the two species commonly and typically used as a toxicology species in drug development; it is of importance to assess the impact of food not necessarily from the point of view of predicting human food effect but more so in ensuring adequate exposure multiples are obtained for toxicokinetic purposes. Few authors have explored rat as a model for predicting food-effect behavior.^[19–21]

Dogs

Pentagastrin-pretreated dogs have been shown to be useful in screening biopharmaceutical properties of new formulations. Coupled with the features that a crossover study design can be easily applied and human food easily administered to these animals, the dog remains one of the commonly used models in assessing the pharmacokinetics of drugs.^[22,23] The disadvantages of using a dog model include dissimilar GI physiology and, hence, differences in pharmacokinetic behavior (for the pentagastrin-untreated dogs), need for modulation of GI physiology using pentagastrin and other physiological agents, and dissimilar drug metabolism/transport between dogs and humans for some compounds. Additionally, dogs are relatively more sensitive to physiological effects of certain pharmaceutical excipients commonly employed in solubilization of poorly water-soluble drugs (e.g., Polysorbate 80 and resultant orthostatic hypotension).

Although gastric emptying time is relatively similar between dogs and humans in the fasted state, the intestinal transit time is almost twice as long in humans.^[24] These apparent differences can be offset by administering pentagastrin pretreatment which allows the gastric acidity, the emptying time, and the small intestinal transit time to closely approximate human conditions, i.e., approximately pH 2, 0.7 and 4 hr, respectively.^[25] Another approach to synchronize the gastric environment in dogs to closely mimic humans includes a combined treatment of intramuscular pentagastrin with intravenous atropine sulfate.^[26]

Pentagastrin is an analog of gastrin that reproducibly stimulates gastric acid secretion and is usually administered intramuscularly prior to biopharmaceutical experimentation in doses of approximately 6–10 µg/kg. Conflicting results in the literature of drugs studied in these pretreated dogs have negated the extensive use of this model. For example, pentagastrin-pretreated dogs were more predictive of the human bioavailability of didanosine than the untreated dogs.^[22] In contrast, data from Kanerva et al.^[27] suggest that the pentagastrin-pretreated dog was unable to reliably predict the absorption of dexamethasone, an acid-labile drug.^[27]

A typical design of a food-effect study in dogs is as follows. Beagle dogs (usually $n = 6-8$) are administered a pharmacological dose of a drug formulation (hard gelatin capsule or tablet) in a randomized or nonrandomized crossover design. Treatment legs may include dosing after an overnight fast (fasted state) and dosing with a low-fat meal, a high-fat meal, or other specialized meals (fed state). The composition of meals that have been administered to dogs can be highly variable. For example, Paulson et al.^[23] administered low-, medium-, and high-fat diets.^[23] The low-fat diet was composed of one slice of toasted white bread spread with 0.5 oz of jelly, 8 oz of skim milk, and 6 oz of orange juice. The medium-fat diet was composed of one slice of toasted white bread with 0.5 oz each of peanut butter and jelly, 1 oz of dry cereal (cornflakes), 8 oz of skim milk, 6 oz of orange juice, and one banana. The high-fat diet was composed of two slices of toasted white bread spread with 1.2 oz of butter, two eggs fried in butter, two slices of cooked bacon, 2 oz of hash brown potatoes fried in butter, and 8 oz of whole milk. These diets were homogenized then administered either in a bowl or with a syringe to the dogs. A suitable washout period separated the treatment legs. Blood samples are collected at predetermined intervals predrug and postdrug administration and pharmacokinetic behavior assessed with and without food.

Pigs and minipigs

The digestive tract of a minipig is anatomically and physiologically similar to that of the human adult digestive tract. In fact, the weanling minipig model has a GI tract that is closely similar to children between the age of 2 and 5 years.^[28,29] Specifically, the similarities exist for the gastric villi, the regulation and the composition of gastric secretions, the transit times as well as in the digestive and the absorptive behaviors.^[30–34] Regardless of these advantages, the use of the minipig in pharmacokinetic assessments has been relatively uncommon. One example of an application to the assessment of food effects in minipigs is the study on the effect of various fat-content diets on the bioavailability of theophylline following a

400-mg single-dose Theo-24.^[35] The observed similarities in the pharmacokinetics of theophylline in pigs and humans led Koritz et al. to suggest swine as a predictive model for the assessment of theophylline bioequivalence in humans.^[36]

FOOD-EFFECT ASSESSMENT IN DRUG DEVELOPMENT: KEY CONSIDERATIONS

Timing of Food-Effect Studies

There are generally two types of clinical pharmacokinetic/pharmacodynamic (PK/PD) studies that may be performed during drug development (Table 2). One is a “pilot” study to obtain preliminary exploratory assessment used for facilitating internal decision making for the progression of a compound and the other is a more formal statistically powered “pivotal” study to provide dosing recommendation for purposes of the drug product label. The key difference is that the pilot study is often powered for large differences and the pivotal study is powered for small differences for *a priori* defined endpoint. The pilot study, which usually uses a developmental formulation and a guess of the therapeutic dose, can also provide valuable information for developing a well-designed pivotal study. Label-driven food-effect assessments are performed in later stages of drug development, particularly when the “market” formulation is available and the therapeutic dose is known from Phase III efficacy studies. Appropriate recommendations for performing such studies are available in the Guidance for Industry issued by the FDA in the United States.

The exploratory assessment of food on the pharmacokinetics of new chemical entities in the drug development chain of events varies largely within companies. This is

Table 2 Typical clinical pharmacology and PK/PD studies in early drug development

I	Clinical pharmacology studies
	Single-ascending-dose safety, PK, and PD
	Multiple-ascending-dose safety, PK, and PD

	Tissue distribution (PET, gamma scintigraphy, etc.) PK

also driven by marketing considerations, competitive advantage, flexibility for dosing options, and the therapeutic index of the drug if known. Several authors have suggested inclusion of an exploratory assessment early in the drug development program because appropriate formulation development may be initiated for drugs exhibiting undesirable food effects.^[37,38] A caveat for this approach is the large number of food-effect studies that may need to be performed if multiple changes are made for the formulation and/or the excipients within them. If multiple-formulation switches occur in a program, it may be worthwhile to delay the food-effect assessment to discount the formulation as a variable.

A convenient method to examine food effects is the inclusion of a food-effect assessment as part of the first-in-man study once the maximum tolerated dose (MTD) is identified. Depending on the drug bioavailability characteristics in animals, physicochemical properties of the drug and preliminary data on whether the drug exhibits dissolution rate-limited absorption behavior, a dose that is 1/2 to 1/4 of the MTD, may initially be used for the preliminary food-effect assessment. This method potentially avoids undesirably high exposures of the drug when adequate safety data are not available. Dose selection will also depend on the predicted therapeutically relevant dose range, the linearity in pharmacokinetic behavior, and the sensitivity of the bioanalytical assay. Typically, the FIM study design includes nonrandomized, noncrossover, single-ascending doses in eight subjects (six active, two placebo), where doses are escalated until an MTD is reached and dosing typically performed after an overnight fast. For example, in the food-effect leg, 0.25–0.5 × MTD cohorts return for a second dose after a wash-out period wherein dose is administered with a standard high-fat meal. This allows within-subject comparison of exposure with and without food, but does not account for period effects. Hence, it is not unusual to obtain inconclusive results with this design. To lend rigor in the scientific assessment of food effect, it may be more desirable to have the food-effect assessment done as part of the first-in-man (FIM) study using a randomized crossover design in eight active subjects.

In general, however, it is recommended to perform specific well-designed food-effect studies with adequate power for large differences to capture meaningful deviations in exposure.

Single vs. Multiple Dosing—Dose Selection

The selection of the appropriate dose in assessing the effect of food on the pharmacokinetics of a drug is an important consideration. Dose selection may be based on several criteria, namely, therapeutically relevant concentrations (if known), safety margin, linear phar-

macokinetics, etc. It is generally required to evaluate a single dose of a drug for such an assessment. However, depending on nonlinear pharmacokinetic behavior and the degree of accumulation (or induction) upon multiple dosing, a multiple dose may be a better option. A multiple-dose study may also be more meaningful if the primary or secondary objective is to evaluate the effect of food on the safety or the pharmacodynamics of a drug, where single-dose administration may not be sufficient to induce meaningful perturbations in pharmacodynamics. An example of this approach is in the multiple-dose administration of the “statin” group of antihyperlipidemic agents for assessing the effect of food on the lipid-lowering efficacy [i.e., LDL-cholesterol (LDL-C) levels] given the slow turnover rate of LDL-C.

Dose selection based on pharmacokinetic profile

The oral absorption of certain highly permeable, poorly water-soluble drugs with low oral bioavailability in the

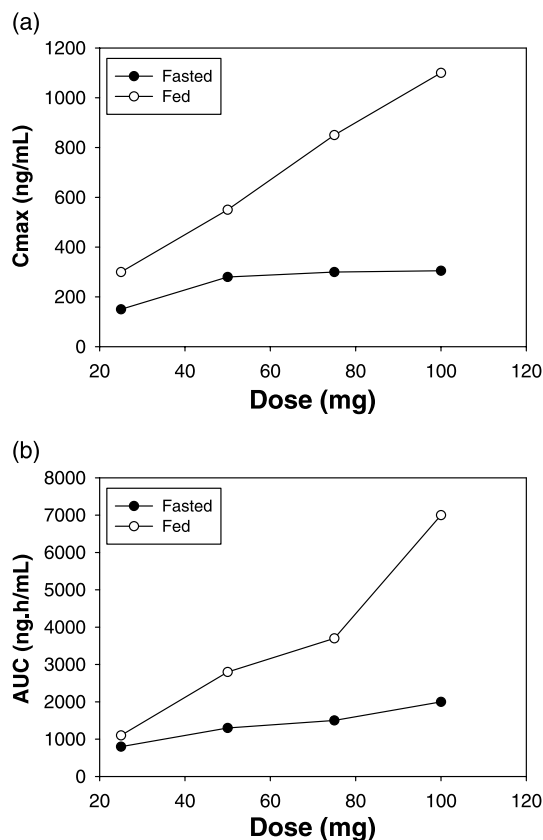

Fig. 3 a: Relationship between dose and C_{\max} for acitretin. (From Ref. [39].) b: Relationship between dose and AUC for acitretin. (From Ref. [39].)

fasted state may be profoundly influenced by the intake of fatty meal. Dose selection for such drugs can be challenging and important. For example, acitretin is a retinoid indicated for the treatment of psoriasis. Depending on the dose of acitretin used, food appears to increase the absorption in a varying manner. Fig. 3a and b highlights the relationship between dose and treatment (fed vs. fasted) on the drug's C_{\max} and AUC. In the fasted state, both the C_{\max} and the AUC reach a plateau at 50-mg dose with minor, if any, increases in exposure at doses higher than 50 mg. In contrast, the drug exhibits almost dose-proportional increases in C_{\max} and AUC over the entire tested dose range up to 100 mg, when the drug is administered with a high-fat meal.^[39] When acitretin is given with food, there is also a decrease in intersubject variability in exposure parameters. These results have important implications for investigational agents exhibiting dissolution rate-limited absorption during drug development as this presents an opportunity for key formulation development to increase bioavailability if safety is not an issue and if formulation options are available. This example also illustrates the need for an early assessment of a food interaction study. In acitretin, the patients in the Phase III pivotal studies were instructed to take their daily acitretin dose with the main meal of the day based on this information.

Dose selection based on PK/PD relationship

A second more germane consideration is dose selection based on PK/PD relationships. Depending on the reference point on a PK/PD chart (Fig. 4), food may have little or profound effect on either PK, PD, or both. For example, drug A shows profound reductions in C_{\max} and AUC, but blood pressure reduction is relatively unaffected by food; it is conceivable that the drug PD is at the maximal effect where large differences in PK leads to minor changes in PD. On the other hand, if the dose of drug B was selected such that its PD is at 50% of maximal effect, then there is much larger PD differences for observed differences in drug exposure.

An example of the former case (drug A behavior) is illustrated in the effect of food on the PK and the PD of pravastatin, a representative statin in the treatment of hyperlipidemia. Although a low-fat, low-cholesterol meal altered the pharmacokinetics of 20-mg pravastatin significantly, no adverse impact on pharmacodynamics (lipid-lowering efficacy) was observed.^[40] Concomitant intake of meals reduced pravastatin C_{\max} by 49% and AUC by 31%, the change in LDL-C-lowering efficacy was minimal (–37% with meal vs. –36% 1-hr premeal). The authors recommend administering pravastatin without regard to meals. It is worth noting here that the LDL-C-lowering efficacy of pravastatin plateaus at ca. –32%

Fig. 4 Representative illustration of PK/PD relationship for a hypothetical drug.

(20 mg) to ca. –37% (80 mg) changes from baseline; at –37%, the PD is already at the flat portion of the sigmoidal PK–PD curve (Fig. 4).^[41] Consequently, even with a change in PK approximating 50%, there is minimal impact on PD. It is unlikely that the PD would be influenced significantly by food for compounds whose PD is at this flat portion of the PK–PD curve than would be the case if the dose selected represented a PD of 0.5 times maximal effect, where there is a much larger variability for PD differences with variability in PK.

Type of Meals

Another key consideration when performing food-effect studies is the type of meal utilized for assessing effect of food on the pharmacokinetics of a drug. Because of differing ethnicities, geographical regions, and variations in the eating behavior of human beings across the world, it is conceivable that the “standard” breakfast, lunch, and dinner will vary extensively. Then it becomes increasingly difficult to assess the true significance of food and its impact on PK/PD and to develop dosing recommendations that are systematically applied to a drug that is prescribed globally.

In order to provide a systematic basis for capturing food-mediated alterations in the pharmacokinetics of drugs, the FDA draft guidance recommends a standard high-fat meal as being composed of “2 eggs fried in butter, 2 strips of bacon, 2 slices of toast with butter, 4 ounces of hash brown potatoes, 8 ounces of whole milk.” Differences in pharmacokinetic behavior may be expected depending on the type of breakfast utilized; for example, an English breakfast is different in composition and caloric value to an American breakfast or a special diet in adherence with ADA recommendations. To derive

meaningful data across these varying types of meals, meals are often categorized in terms of carbohydrate, protein, and fat content as “high-fat,” “low-fat,” “high-protein,” or “high-carbohydrate” diet. An alternate categorization is based on the caloric value of the meal itself, as “low calorie” or “high calorie.” The influence of differing breakfast compositions and the influence of a solid vs. a liquid (whole milk) meal were investigated by Colburn et al. for etretinate.^[42] The drug was administered in the fasted state or in the fed state with a standard high-fat breakfast, a standard high-carbohydrate breakfast, and whole milk (16 oz). Etretinate concentrations in plasma were greater when given with a high-fat meal and whole milk compared to the fasted state or when given with a high-carbohydrate meal. Meals with differing fat contents can also influence drug absorption and disposition by influencing physiology. It is known that higher levels of fat may inhibit gastric emptying. Moreover, the GI transit times are different for solid and liquid meals and this may impact the pharmacokinetics of a drug. Table 3 is a partial list of some of the components in meals that have an effect on drug absorption, metabolism, and clearance. The lack of consistency in the scientific literature on the type of meal used in the investigation prohibits data comparisons across populations unless such differing compositions are used in a single study.

Of more importance in relation to the influence of food on absorption is the rate of blood flow in the capillary system. Food may cause an increase in splanchnic blood flow leading to alterations in drug absorption, depending on the ingredients present in the food that is ingested. Closely tied into this principle is the extent to which a given drug is extracted by first-pass metabolism when traversing through the liver via the portal circulation. Both the type and the size of meal can influence splanchnic blood flow. Using a noninvasive technique for the assessment of hepatic haemodynamics using ra-

diocolloid imaging, Walmsley et al. assessed the influence of meal on hepatic, mesenteric, and splenic arterial effective blood flows.^[43] They showed that both the total effective liver blood flow and the mesenteric arterial effective flow increased by 28–69% after eating. It is known that long-chain fatty acids stimulate human intestinal blood flow.^[44]

It has become increasingly evident that several ingredients in food or components of a meal can influence drug metabolism and clearance via inhibition of cytochrome P450 isozymes or modulation of drug transporters such as p-glycoprotein.^[45–53] These ingredients include vegetables and fruit products and components such as St. John’s wort, garlic, grapefruit juice, certain type of orange juices, apple juice, red, black, or white pepper.^[45–53] Red wine and green tea also have ingredients that can alter the metabolism/clearance of a drug. In order to differentiate these influences from those arising from the altered GI physiology, the drug development program may need to include separate food and metabolism–transporter interaction studies to assess the overall impact on dosing recommendations.

Time of Meal Consumption Relative to Dose

The time of meal consumption relative to dose has important implications for compounds whose pharmacokinetics are severely impacted by food. The extent of food-mediated alterations in pharmacokinetics are influenced by the time interval between ingestion of food and intake of drug. Notably, as the time elapsed between meal ingestion and drug intake becomes longer, the less severe the effect of food on the pharmacokinetics of a drug would presumably be. Consider the following example. If one were to fix the meal intake as a constant and to vary the time of intake of a meal, then differences in the rate and the extent of drug absorption may be observed. Fig. 5 relates AUC as a function of time of meal intake for tacrolimus (FK506, Prograf) following a single 5-mg oral dose.^[54] The treatments were: A) 10-hr fast; B) drug intake 1 hr before breakfast; C) drug intake immediately following consumption of the breakfast; and D) drug intake 1.5 hr after beginning consumption of the breakfast. As expected, tacrolimus absorption was the highest in the fasted state.^[54] The lowest impact on bioavailability was when taking the drug 1 hr prior to a meal; the highest impact was when tacrolimus was ingested immediately after a meal (treatments C and D).

Marathe et al. have investigated the effect of food on the pharmacokinetics of avitriptan in a systematic manner as part of the avitriptan drug development program. In the first study,^[55] they showed that concomitant ingestion of food significantly reduced avitriptan bioavailability. Specifically, mean C_{max} and AUC were reduced 70% and

45%, respectively, while T_{\max} was delayed from 45 min to 2 hr when avitriptan was administered as a 50 mg capsule 5 min after a standard high-fat meal. Because avitriptan was developed as a treatment for migraine, this dramatic food effect has important implications for the developability of the drug for this indication. In the second study, Marathe et al. designed a meal-timing study where avitriptan was administered after an overnight fast and at 0.5, 1, 2, and 4 hr after intake of a standard high-fat meal.^[56] There was a meaningful relationship between avitriptan bioavailability as a function of time interval between dose and meal intake with the impact of food decreasing over time. Mean C_{\max} decreased by 61%, 58%, 50%, and 35% after 0.5-, 1, 2-, and 4-hr postmeal, respectively; mean AUC decreased by 35%, 31%, 34%, and 19% after 0.5-, 1, 2-, and 4-hr postmeal, respectively. Median T_{\max} values were 0.5 hr (fasted), 1.5 hr (0.5- and 1-hr postmeal), 1.25 hr (2-hr postmeal), and 0.75 hr (4-hr postmeal). In a later study by the same authors, scintigraphic analysis showed that avitriptan was rapidly absorbed from the upper small intestine after emptying from the stomach.^[57] Gastric emptying was slow and continuous in the fed state leading to extended absorption. The authors also attributed the high intrasubject variability in C_{\max} and AUC to variability in gastric emptying under fasted and fed conditions.

A similar study was reported by Laitinen et al.^[58] on the effect of time of meal on the bioavailability of the bisphosphonate drug clodronate.^[58] Exposure (AUC) was the highest when clodronate was administered 2-hr premeal, followed by a 1-hr premeal (91% of 2-hr premeal AUC), a 0.5-hr premeal (69% of 2-hr premeal AUC), with meal (10% of 2-hr premeal AUC), and a 2-hr postmeal (34% of 2-hr premeal AUC). Although the 2-hr premeal does not present a “true” fasting state, there was a measurable difference between these short time intervals premeal and postmeal leading the investigators to conclude that clodronate be administered at least 0.5 hr

prior to breakfast. The closeness of this prescribed time of drug intake to the meal ensures some balance of patient compliance with minimally acceptable compromise on the impact on drug absorption.

For a drug with a wide therapeutic margin, such variations in drug absorption relative to timing of a meal may be inconsequential in terms of clinical relevance; however, the same cannot be said for a drug with narrow therapeutic margin.

Type of Formulation

The type of formulation used, the excipients contained in the formulation as well as the particle size of the drug substance all may influence drug absorption and, thus, confound the observed food-effect behavior for a given drug.^[59–63] For example, a highly water-soluble drug may be formulated in a tablet that contains a poorly water-soluble polymer excipient that influences release of the drug from the matrix and subsequent dissolution properties of the tablet. Certain hydrophilic polymers, such as hydroxypropylmethylcellulose, have been implicated in dose dumping of modified- or controlled-release formulations in the presence of food. The use of varying excipients within formulations are often the cause of conflicting data for observed food effects. Whereas some excipients, such as mannitol, influence drug absorption by altering transit times, others, such as PEG-300, Cremophor EL, and Polysorbate 80, inhibit p-glycoprotein and other drug transporters^[59,60,63].

In a drug development program, it is sometimes necessary to change the formulation depending on drug development timelines and availability of drug substances to meet the needs of clinical pharmacology and PK/PD studies in a timely manner. For example, the formulation may change from an aqueous suspension in the first-in-man study to a capsule formulation in proof-of-concept study to, eventually, a market formulation that would be a tablet formulation. Each time such formulation changes are made, a new food-effect study may need to be performed to assess the influence of the altered formulation on the observed food effect to design the Phase III study in an optimal manner. To minimize the number of food-effect studies performed due to formulation changes, it is essential to maintain consistent formulation strategy across the drug development phase. Inclusion of excipients should occur based on informed input from a variety of functional areas including pharmaceutical sciences, clinical pharmacology, clinical PK/PD, and drug safety. A pivotal food-effect study needs to be performed using the same formulation used in Phase III pivotal efficacy trials or the market formulation so that appropriate dosing recommendations with regard to meals are provided.

Site of Drug Absorption

Absorption of drugs from the GI tract differs extensively depending on the intrinsic properties of the drug. For example, a drug may be absorbed from the upper GI tract or throughout the GI tract. This will have important implications for food effects as well as for other applications such as developing modified-release formulations or demonstrating bioequivalence of a test formulation vs. the reference formulation. For a drug that has an absorption window of the upper GI tract, a delay in T_{\max} as mediated by food may lead to suboptimal absorption.

CONCLUSION

It is very clear that food can have significant pharmacokinetic and pharmacodynamic consequences for drug substances. Although not discussed in this article, food can also have deleterious effects on efficacy and safety of a product. A growing body of literature now points at many pharmaceutical excipients that are typically used in drug development cycle to influence drug disposition by modulating metabolism and efflux properties of drugs. Whether the information on food effects is derived for internal company decision making and developability considerations or for dosing recommendations with the final market formulation, understanding the myriad and often complex actions mediated by food is critical in drug development. A rationale selection of available choices within the context of a well-designed and adequately powered clinical study will provide important clues for the drug development scientist to: 1) enable well-designed late-stage clinical efficacy trials; 2) optimize the formulations for early- and midstage developmental compounds; or 3) provide prescribing options to the physician for optimal patient compliance on soon-to-be-marketed products.

PHARMACOPEIA STANDARDS: *EUROPEAN PHARMACOPOEIA*^a

Agnès Artiges

European Directorate for the Quality of Medicines (EDQM), Council of Europe, Strasbourg, France

INTRODUCTION

The purpose of a pharmacopoeia and particularly of the *European Pharmacopoeia* is to promote public health by providing common standards recognized by health authorities and all those concerned with the quality of medicines. Such standards are to be of appropriate quality as a basis for the safe use of medicines by patients and consumers. Their existence facilitates the free movement of medicinal products in Europe and ensures the quality of medicinal products exported from Europe.

As noted previously (1), the status of the *European Pharmacopoeia* is based on the existence of an international convention created under the aegis of the Council of Europe (2). The primary characteristics and goals of the *European Pharmacopoeia* are described in this convention. The following chapters present its evolution in the area of the quality of medicines to fulfill the needs of European and International Harmonisation for both regulatory authorities and industries.

THE THIRD EDITION AND ITS CHARACTERISTICS

The *European Pharmacopoeia* plays an important role, not only for well known products manufactured for many years but also for new types of medicines by:

1. elaborating unified specifications for substances from different sources;
2. publishing validated methods;
3. providing common reference substances;
4. producing monographs that are clear (description of impurities controlled by the monograph); and
5. providing a forum for users and other organizations.

The 3rd Edition was published in 1996, and an annual supplement is published in midyear (supplement 1998 in 1997, supplement 1999 in 1998, supplement 2000 in 1999).

^aThroughout the text of this article, the European spelling *pharmacopoeia* is used

All new editions of the *European Pharmacopoeia* now include the year their texts entered into force in their titles; this should make them easier to use. Each supplement is cumulative and replaces the previous one and includes on average approximately 100 new monographs and more than 150 revised texts.

It is available in both print and electronic versions that are published by the European Directorate for the Quality of Medicines (EDQM) of the Council of Europe (3).

Content

The 3rd Edition includes an introductory chapter (General Notices), a chapter on general methods and texts and reagents, followed by monographs in alphabetical order on all type of substances used in the preparation of drug products including excipients (4) and herbal drugs (5). A few monographs on preparations such as radiopharmaceuticals, vaccines, and some hormone preparations (e.g., insulin) are included. There is also a monograph on homeopathic preparations.

The last chapter of the book is focused on general monographs for dosage forms.

We comment here on the main categories of monographs.

General notices

This introductory chapter summarizes the characteristics of the legalities of the *European Pharmacopoeia* and gives the principal definitions. It explains the legal significance of each part of the *Pharmacopoeia* and the role of each section of a monograph. This chapter is essential reading when reference must be made to a monograph of the *European Pharmacopoeia*.

Monographs on chemical substances

All such monographs are presented in the same format, which is described in the "Technical Guide for the Elaboration of Monographs of the European Pharmacopoeia" (6). This guide contains the same concepts as those defined in Community guidelines, which themselves contain the guidelines adopted jointly at the international level, via the International Conference on Harmonisation (ICH). Hence, the two guidelines on analytical validation

are integrated into this technical guide and are even supplemented by specific chapters on the principal methods of analysis (such as spectrophotometry and liquid chromatography, etc.).

The ICH guideline on impurities is also integrated into the technical guide, and the guideline on residual solvents has been integrated into a general chapter of the *European Pharmacopoeia*.

European Pharmacopoeia monographs on chemical substances have therefore been modified in connection with these changes for better control of the impurity profile of substances produced by numerous manufacturers using diverse methods of synthesis. Each revised or new monograph now contains an impurities section at the end that describes the list of impurities known to be detectable by the monograph. Whenever necessary, this impurities section consists of two parts: the list of qualified impurities and the list of impurities that can be detected analytically by the monograph but that are not qualified according to the ICH guideline. The list of impurities includes both the chemical nomenclature and the graphic formula, which makes the section easier to use.

In addition, the presentation of monographs has now been supplemented by the establishment of a procedure for Certification of Suitability of Monographs (see later), thus fully satisfying the requirements of Directives 75/318/EEC for medicines for human use (7) and 81/852/EEC for medicines for veterinary use (8), and the EU note for guidance, "Summary of Requirements on Active Substances in Part II of the Dossier" (9).

Finally, the identification section of these monographs has also been modified to clarify the presentation of monographs that give alternative series of identification tests. The status of this section is clearly defined in the general notices. They specify that when there are two identification series, the first, more complete series will be fully implemented by manufacturers of active substances; the second series is an alternative with less sophisticated analytical methods, but its use requires that the product be traceable from the manufacturer (which carried out all the methods described in the first series) to the user.

Monographs on biological substances

All types of biological medicines such as hormones (10), vaccines for human use (11–13), vaccines for veterinary use (14), and blood products (15) are covered in specific monographs.

Important conceptual changes have also been made to the establishment of this type of monograph to satisfy the needs of Community licensing and to keep up with progress in that field. The following changes merit special attention:

1. the introduction of a production section;
2. the replacement, whenever possible, of tests involving the use of laboratory animals; and
3. the elimination of the test for abnormal toxicity and its replacement by the test for endotoxins (LAL).

The role of the production section is described in the General Notices. The requirement described in this section applies primarily to the manufacturers of the substance in question and to the body of inspectors responsible for checking compliance with the prescriptions of the *European Pharmacopoeia* or with the information given in the licensing dossier.

The tests described in this section cannot necessarily be carried out on the finished product by outside analysts, as with the tests described in the sections on identification, tests, and assay. Nevertheless, they play a major role to guarantee the quality of the substances in question.

In recent years, the European Pharmacopoeia Commission has elaborated a policy of replacing the use of animals in quality control testing of medicines in parallel with the application of the corresponding Convention of the Council of Europe. A sizeable program has been set up to apply the 3-R concept (refine, reduce, replace). To this end, the Council of Europe, represented by the EDQM, and the Commission of the European Communities are now working on an extensive standardization programme (16) to set up collaborative studies to:

1. evaluate, develop, and improve the standardization of test methods for biologicals;
2. prepare European working standards;
3. apply the 3-R concept to replace the use of laboratory animals; and
4. continue the harmonization of test methods for biologicals in Europe and, if possible, the world, in collaboration with the World Health Organization (WHO).

These collaborative studies have led to the establishment of European working standards. Consequently, the titers and potencies of biological products will be expressed with respect to the same reference standard. The existence of reference standards recognized throughout Europe enables national control agencies and manufacturers to avoid costly duplications of work on secondary standards that could otherwise lead to disagreements.

Collaborative studies are also aimed at the validation of alternative reference methods. Comparative tests of various analytical or operating procedures can be used to validate a method of choice or even to establish a close correlation among a method involving tests on

animals, an in vitro biological method, and a method based on physicochemical analysis, thus facilitating the replacement of one method by another in the future.

To facilitate communication and understanding among partners, the results of collaborative studies are published in special issues of *Pharmeuropa* (17).

Monographs on dosage forms

A new chapter has been introduced that brings together all the monographs describing dosage forms, and whenever necessary, the monographs have been supplemented by technological tests and harmonized so that the chapter constitutes a coherent whole.

It should be noted that this chapter and the previous EEC guideline published in 1991 on "authorised terms for dosage forms, routes of administration and containers" were revised together by the European Pharmacopoeia Commission at the request of the Commission of the European Communities.

Thus, both tasks were carried out in parallel and coherently: on the one hand, the revision of all the monographs of the *European Pharmacopoeia* and on the other hand, the revision of the Community guideline on authorized terms.

This guideline has been replaced by a revised version elaborated in the *European Pharmacopoeia* called "Standard Terms" (18); it has been translated into all the languages of the Community. Indeed, not only does this document give the terms in the languages of the Community, but it also includes terms in the national languages of several delegations to the *European Pharmacopoeia* that are not members of the European Union but that also wish to provide a translation in their language. The revised document will therefore list terms in 21 European languages (Bulgarian, Croatian, Czech, Danish, Dutch, English, Finnish, French, German, Greek, Hungarian, Icelandic, Norwegian, Italian, Polish, Portuguese, Slovak, Slovenian, Spanish, Swedish, and Turkish).

This relatively large document, which covers both human and veterinary medicines, is published as a special issue of *Pharmeuropa*. The first version was published in November 1996, then revised yearly; the next revised version was published in February 2000. This will produce a harmonious and coherent whole that can be used throughout Europe. The terms are mandatory for applications and summaries of product characteristics for EU centrally and decentrally authorized products.

The list can be extended on request if justification is provided. A specific procedure has been set up (18). Forms are also available on the EDQM Web site.

General monograph on methods of manufacture

Another way to address the quality of the monograph is to apply the concept developed in the 1980s and 1990s, which is that one cannot control the quality of a product simply by testing the finished product. One is controlling only what is being sought. The quality of a product has to be included from the very beginning and maintained throughout the manufacturing process.

To avoid repeating key points of policy in its texts, the European Pharmacopoeia Commission's current approach is to prepare general monographs that cover all the specific monographs but that can also be referred to for substances that have no monograph in the *European Pharmacopoeia*. Thus, new general monographs on the method of production have been prepared, such as the monograph "Products of Fermentation" (19), "Products of r-DNA Technology" (20), and "Products with Risk of Transmitting Spongiform Encephalopathy" (21).

In addition, compilers of the *European Pharmacopoeia* have been asked to add a production section to the monographs for specific substances. The production section gives key points but not all the details that refer to a specific manufacturer. In addition to the production section in specific monographs, general concepts in line with new ICH guidelines are also identified. Such details are described in the application for a Certificate of Suitability by each manufacturer (see above).

Revision of Monographs

The European Pharmacopoeia Commission is very attentive to updating its monographs. Revisions can be made at any time if a pharmacopoeial or licensing authority requests a particular change. The European Pharmacopoeia Commission has defined its criteria for revision of monographs when:

1. poor quality products appear on the market;
2. a request is made in connection with the certification procedure;
3. there is a public health risk (presence of nonqualified impurities, risk of falsification, etc.);
4. the analytical methods are no longer adequate;
5. certain tests in a monograph are no longer applicable;
6. reagents are unavailable; and
7. the patent is close to the expiry date.

In addition, a more extensive program of revisions corresponding to new developments in methods is carried out every 5 years. Such revisions take account of new guidelines from the licensing authorities and the need for harmonization within families of substances.

How and by Whom Are Texts Elaborated?

The *European Pharmacopoeia* is elaborated by a Commission made up of national delegations from regulatory authorities, with decisions requiring a unanimous vote by the delegations (2). (Today, the Convention has been signed by 27 European countries^b including all EU members and by the EU Commission itself. Nine other European^c and eight Non-European countries are also observers.)

The monographs are elaborated by the groups of experts appointed by the European Pharmacopoeia Commission based on proposals by the national delegations. The experts participating in this work are from industry, universities, and national control laboratories.

The *European Pharmacopoeia* has progressively been replacing the national pharmacopoeias. Nevertheless, we need to emphasize the major role played by the national pharmacopoeia secretariats in the elaboration of the common European work. Indeed, they are in the best position to identify national needs and to organize:

1. consultation with the pharmaceutical, chemical, and biological industries that manufacture in their territories (consolidated comments sent to the secretariats of the *European Pharmacopoeia*);
2. consultation with other governmental organizations impacted by the work (e.g., ministries of industry or agriculture); and
3. collaboration with other departments in medicine-related agencies such as licensing authorities, national control laboratories, and inspection.

Finally, the national secretariats play an important role in providing information at the national level on how European rules are elaborated, and any national text is prepared and revised in compliance with the *European Pharmacopoeia*.

Before final adoption, all texts and monographs are published in *Pharmeuropa* for 4 months of public inquiry. For European countries, comments should be sent through the national secretariat; for non-European companies, comments should be sent directly to the EDQM-Council of Europe (B.P. 907, F-67029 Strasbourg Cedex, France). *Pharmeuropa*, the users's forum is a quarterly publication prepared and published by the EDQM.

^bAustria, Belgium, Bosnia-Herzegovina, Croatia, Cyprus, Czech Republic, Denmark, Finland, France, The Former Yugoslav Republic of Macedonia, Germany, Greece, Hungary, Iceland, Ireland, Italy, Luxembourg, the Netherlands, Norway, Portugal, Slovakia, Slovenia, Spain, Sweden, Switzerland, Turkey, the United Kingdom of Great Britain and Northern Ireland and the European Union.

^cAlbania, Bulgaria, Estonia, Latvia, Lithuania, Malta, Poland, Rumania, Ukraine.

Implementation by the Parties

The *European Pharmacopoeia* is a common supranational document that supersedes any national texts for the signatory parties. A common implementation date is adopted by the European Pharmacopoeia Commission for each supplement/edition (or individual text for rapid revision) that enters into force by means of a resolution of the Council of Europe/Public Health Committee.

Although the signatory parties are bound by the texts and specifications of the *European Pharmacopoeia* published by the Council of Europe, they are free to implement them in ways that are compatible with their technical, legal, and administrative regulations. Thus, different procedures are used in different countries.

A majority of members implement directly the volume published by the Council of Europe; others continue to issue a national pharmacopoeia that republishes all or some of the harmonized European texts translated if necessary into the national language or style (Austria, Bulgaria, the Czech Republic, Germany, Greece, Hungary, Portugal, Spain, Switzerland, and the United Kingdom). In all cases, it is the European text that is implemented and made legally binding, superseding any translation in cases of doubt.

CERTIFICATION OF SUITABILITY OF MONOGRAPHS

This unprecedented procedure for Certification of Suitability of Monographs of the *European Pharmacopoeia* was established a few years ago (22). Why? For centuries, pharmacopoeias were designed to be references that were complete and obligatory in themselves. However, in the 20th century, with the growth of world trade, the EU licensing authorities found that they increasingly had to ask manufacturers to provide in their licensing applications complete details on the synthesis of their product to demonstrate that the product was suitably controlled by the *European Pharmacopoeia* monograph. Thus, it then became apparent that it was absolutely necessary to reconsider how this essential information could be made available to those who needed it without duplication of work by the *Pharmacopoeia* compilers and licensing authorities.

To solve this problem, it was necessary not only to adapt the content of monographs to new needs but also to set up a procedure for Certification of Suitability that would establish a link between licensing and the *Pharmacopoeia* in this area.

As noted above, the content of monographs was supplemented where relevant by production and impurities sections to make these monographs more complete and clear (23).

The certification procedure is a complement and bridge between the public standards described in the *European Pharmacopoeia* and the need to prepare a file for licensing. This procedure is a result of much common discussion and agreement among the partners concerned. It was in fact made to measure its collaboration not only with the European regulatory authorities so that they could rely on it totally and recognize unreservedly its validity but also with the industries so that they could be absolutely sure of the protection of industrial property.

On the basis of the data collected during the elaboration of the monograph and the specific data provided by a specific manufacturer on a specific substance, the Certificate of Suitability certifies that both types of data make it possible to conclude that the quality of the substance corresponds to the quality defined in the *European Pharmacopoeia* monograph.

In principle, a certificate can be granted for any substance (active substances, excipients) such as organic or inorganic substances, substances produced by fermentation as indirect gene products, and products with risk of TSE for which a monograph published in the *European Pharmacopoeia* exists. Excluded, however, are biological substances such as proteins, products obtained from human tissues, vaccines, blood products, and preparations.

The certificate, granted for 5 years, may include additional specifications (methods and limits) when monograph specifications do not fully control the purity of the substance (e.g., control of residual solvents, specific impurities, etc.).

The procedure is described in Resolution AP-CSP (99) 4, together with the content of the file to be submitted (24). This procedure, lists of certificates granted (420 at the end of January 2000), and lists of assessors are published regularly in *Pharmeuropa* and on the EDQM Web site (<http://www.pheur.org>, direct link with the Certification Unit: cert@pheur.org).

Certificate of Suitability Versus European Drug Master File

Although both procedures have the same aim and require dossiers with exactly the same contents, the certification procedure is especially designed to cover substances for which there is a monograph in the *European Pharmacopoeia*, whereas the European Drug Master File procedure is aimed at substances for which there is no *European Pharmacopoeia* monograph.

In conclusion, a procedure makes it possible to avoid duplication of work not only by manufacturers of raw materials and manufacturers of medicines (finished products) when they prepare licensing dossiers but also by the licensing authorities and pharmacopoeia authorities when they assess these dossiers. Differences among the various European licensing authorities in approach and assessment of compliance with *European Pharmacopoeia* monographs are also avoided, and clearer communications are facilitated. Finally, the procedure allows *European Pharmacopoeia* monographs to be constantly updated to keep up with new developments in the world market.

TOWARD THE 4TH EDITION

European Pharmacopoeia authorities have decided to publish a fourth edition. For this purpose, both the technical guide and the style guide have been revised, and more general monographs have been or will be elaborated.

Technical Guide

This guide (6) is intended for the experts who participate in the elaboration of *European Pharmacopoeia* monographs; it establishes the general rules to be followed. This document specifies the philosophy behind the choice of techniques for identification testing of a substance and for the determination of the limit contents of impurities and the methods used to detect them.

The 2nd Edition had been revised particularly to be in line with the ICH guideline. The 3rd Edition was published in February 2000.

Style Guide

This is an internal guide for professionals of the *European Pharmacopoeia* and for the secretariat to make the monograph style more uniform in English and French, the two official languages of the Council of Europe. The aim is to provide the means of drafting clear, unambiguous texts. The style, which will appear in the 4th Edition, is more telegraphic than that used in the 3rd Edition.

General Monographs

The fundamental goal of the *European Pharmacopoeia* is to promote the harmonization of standards for medicinal products in the member states and in view of this, the European Pharmacopoeia Commission considers that it is desirable and possible to extend the scope of general

monographs to encourage a convergence of approach by licensing authorities and thus avoid future difficulties in harmonization.

The *European Pharmacopoeia* contains a number of general monographs that cover categories of products defined by the:

1. presentation of the medicinal product (dosage form monographs such as "Tablets," "Eyedrops," etc.);
2. nature of the product (radiopharmaceutical preparations, vaccines for human use, etc.); and
3. methods of production (products of fermentation, products of rDNA technology, products with TSE risks).

New general monograph on substances for pharmaceutical use (active substances and excipients) (25) had been prepared to include in the *European Pharmacopoeia* the ICH guideline for residual solvents and the ICH qualification threshold for new impurities without revising each individual monograph concerned. In addition, the monographs are used to simplify the *Pharmacopoeia* requirements concerning sterility, bacterial endotoxins, and pyrogens tests contained in individual monographs. However, because it is the policy of the Commission to add these requirements whenever it is considered to be appropriate, a general regulation will now replace the regulations in individual monographs.

Furthermore, the monograph gives a definition of the terms "active substance" and "excipients"; it explains the policy of the Commission concerning polymorphic forms, active substances of special grade, processing of active substances with and without the addition of excipients, and the two sets of identification tests that may be contained in a monograph.

The status of these general monographs will be defined in the chapter, "General Notices."

International Harmonization with USP and JP

This review will not be completed without highlighting the close relationship that has developed since 1990 among the European, Japanese, and U.S. pharmacopoeias. They cofounded the Pharmacopoeial Discussion Group, which is working diligently for harmonization at the world level and which participates in the ICH program (26–28). This group meets regularly (twice a year) in Europe, Japan, and the United States. Approximately 50 monographs on excipients and 20 general methods of analysis proposed by national associations of manufacturers of pharmaceutical products have been selected for convergence and harmonization in the three pharmacopoeias.

A special section of the *European Pharmacopoeia* quarterly journal *Pharmeuropa* is now dedicated to this activity. Joint open conferences organized by the five pharmacopoeias, in Verona, Italy (on biotechnology products in April 1993); St. Petersburg, FL (on excipients in 1994); Barcelona, Spain (on microbiological tests in 1996); Seville, Spain (on dosage-form pharmacotechnological tests in 1998); and Strasbourg, France (on new trends in biologicals in 1999) regularly brought together specialists from all over the world.

PHARMACOPEIAL STANDARD: JAPANESE PHARMACOPOEIA^a

Mitsuru Uchiyama

Japan Pharmacists Education Center, Tokyo, Japan

INTRODUCTION

The *Pharmacopoeia of Japan* (JP), which dates back to 1886, provides the official standards and test methods for regulating the properties and quality of drugs important for medical treatment. In general, the standards set forth in the JP affect not only those articles included in the JP but all drugs and drug products in circulation in Japan. The JP has played an important role in ensuring and improving drug quality through all phases of development, application, evaluation, distribution, inspection, and consumption before and after manufacture. Thus, revision of the Pharmacopoeia must occur within a structure and system that are unaffected by bias and undue influence of any party for its standards to be recognized as credible and reliable for ensuring drug quality.

FRAMEWORK

The JP is currently published by the Ministry of Health and Welfare through the Committee on the JP of the Central Pharmaceutical Affairs Council (CPAC), pursuant to the Pharmaceutical Affairs Law. The Committee on the JP includes a subcommittee consisting of 12 advisory panels, each concentrating on one of the following subject areas: principles of revision; selection of articles; medicinal chemicals; biologics and biologicals; general test methods; physical test methods; biological test methods; preparations; crude drugs; nomenclature; and pharmaceutical excipients.

The panel members are scientists from national institutes, universities, and prefectural laboratories, who are appointed every 2 years by the Minister of Health and Welfare. As a rule, a panel member is not appointed for more than 8 consecutive years. A certain number of liaison members from industry serve on 10 of the 12 panels. In contrast, the panels responsible for nomenclature and selection of articles do not include liaison members from industry.

^aThroughout the text of this article, the European spelling *pharmacopoeia* is used.

The JP secretariat is part of the Evaluation and Licensing Division of the Pharmaceutical and Medical Safety Bureau of the Ministry. The secretariat works under the scientific and technical support of the National Institute of Health Sciences (NIHS). The Pharmaceutical and Medical Safety Bureau is a new organization, established in July 1998, as a result of a reorganization of the former Pharmaceutical Affairs Bureau. The CPAC itself will be terminated in January 2001 in response to further reorganization of government offices and will resume operation as the council responsible for both pharmaceutical and food sanitation affairs.

REVISION PROCESS

Revision Cycle

The Pharmaceutical Affairs Law stipulates that the JP be revised at least once every 10 years. However, beginning in 1967, because of the rapid progress and changes in medicinal and pharmaceutical research and development, the revision cycle of the JP has been reduced to once every 5 years. Thus, the 11th and 12th editions were published in 1986 and 1991, respectively, and the most recent edition, the 13th, was published in April 1996. An English version has subsequently been released. In the event of a discrepancy between the Japanese original and its English translation, the former is considered official. The English version of the JP is available through Yakuji Nippo, Ltd. (Kanda Izumicho 1, Chiyoda, Tokyo 101-8648, Japan) (1).

A supplement, the first in JP history, was published in October 1988, 2 years after publication of the 11th edition. The Ministry published two supplements to the 12th edition in October 1993 and December 1994, respectively. The first and second supplements to the 13th edition became available in December 1997 and December 1999, respectively. The 14th edition will be published in April 2001.

Principle of Revision

The current fundamental goal and most important consideration of the JP revision, to which the evaluation

of new drug quality also conforms, is to obtain pharmaceuticals of consistent quality, but not necessarily of higher purity, to provide maximum benefit to the consumer. The specification should be sufficient to at least identify and ensure adequate quality, and the analytical procedures should be accurate and easy to perform. However, a proper balance between accuracy and ease of use needs to be maintained to allow for this analysis. Although extremely high accuracy is not necessary, the limit of detection or the limit of quantitation, as well as the recovery in purity tests, should be validated by sufficient data. Hazardous chemicals should be avoided, and experimental testing on animals should be minimized.

Revision Process

Proposals for revision of the JP monographs or test methods can be submitted through the JP secretariat in the Pharmaceutical and Medical Safety Bureau by any concerned individual or organization. The proposed monograph, either for a new entry or for a revision, is then drafted by a panel member or an industry professional. New or revised test methods are handled in a similar manner. To accomplish this, panels are assisted by the Japanese Pharmaceutical Manufacturers' Associations of Tokyo and of Osaka, the Japan Pharmaceutical Excipients Council, the Crude Drugs Association of Tokyo, the Federation of Crude Drugs Association of Japan, and the Japanese Society of Hospital Pharmacists.

The draft monograph is reviewed by the two panels on Medicinal Chemicals. The Panel on Medicinal Chemicals I adopts new entries, whereas the Panel on Medicinal Chemicals II revises existing monographs. The drafts for traditional medicines and pharmaceutical excipients are reviewed by the Panel on Crude Drugs and the Panel on Pharmaceutical Excipients, respectively. Nomenclature and chemical structures are examined by the Panel on Nomenclature once the draft monograph has been finalized. Additions or changes to the three general test methods (chemical, physical, and biological) and reagents are addressed by the corresponding panel for each test method.

The establishment of reference standards is adopted at the suggestion of the related panels after due consideration of the opinion of the NIHS, which is directly responsible for establishing those reference standards in cooperation with the Society of Japanese Pharmacopoeia. The Society of Japanese Pharmacopoeia (Shibuya 2-12-19, Shibuya, Tokyo 150-0002, Japan) is a nonprofit private organization that carries out activities in support of MHW administration and regulation of pharmaceuticals. The Society

plays several roles and, in particular, makes reference standards available including a part of the pharmacopoeial reference standards. It also distributes *Pharmacopoeia* and related informative documents, such as the *JP Forum*, and convenes public meetings and symposia.

JP Forum

After finalization by each panel, all drafts for revision are opened for public comment through the *JP Forum*, a vehicle for notification and commentary (2). The *JP Forum* is published quarterly by the Society of Japanese Pharmacopoeia under the auspices of the JP secretariat. The *JP Forum* was first published in January 1992 as a medium for both local and international communication. It will continue to provide a more open revision process for the JP and announce revisions and future directions of the JP committees. The *JP Forum* is issued in Japanese, primarily for domestic users, but articles related to the international community and commentary will be issued in English concurrently with the Japanese version. Therefore, we anticipate that the *JP Forum* will aid in the process of international harmonization and will promote a better understanding of and increased trust in the JP.

After comments are reviewed and changes are made, the revised draft is reviewed by the Committee on the Japanese Pharmacopoeia and then by the Executive Committee of the Central Pharmaceutical Affairs Council before it is submitted for publication in the JP.

Time Frame

Regarding the interval between new drug approval and the adoption of a pharmacopoeial monograph in Japan, the first monograph generally does not appear in the JP until publication of the outcome of its reevaluation. The term of current reevaluation for a new active ingredient is generally 6 years after approval. The reevaluation period is needed to ensure the safety and efficacy of new drugs. For a particular drug, such as an orphan drug, the reevaluation period is 10 years after approval.

In addition, not all new drugs are listed in the JP, and the Panel on the Selection of Articles decides which drugs should be listed based on their importance in terms of medical treatment. The innovators sometimes do not want their drugs to be listed in the JP, concerned that such listings will trigger the introduction of generic brands. As a result, the JP contains fewer monographs than does the *U.S. Pharmacopoeia–National Formulary* (USP–NF). The JP 13 contains 1292 monographs, which is approximately one-third the number included in the USP–NF.

SIZE, SCOPE, AND PRESENTATION OF JP 13

The JP 13 is a single volume comprising two parts. Part 1 includes 824 monographs of widely used drug substances and their preparations, for 532 organic and inorganic chemical ingredients, 187 preparations (single-ingredient dosage forms), 91 antibiotics, 11 radiopharmaceuticals, and 3 medicinal gases. Part 2 includes 468 articles, for 106 mixed preparations, 132 pharmaceutical excipients, 172 traditional (crude) drugs, 30 biologics, 21 miscellaneous substances of plant or animal origin, and 7 surgical dressings. In addition to the monographs, the JP contains sections on notices of importance, rules, standards, test methods, and apparatus commonly applicable to any of its articles. There are 131 JP Reference Standards.

The General Notices in the JP provide specific definitions. Some examples are:

1. definitions of standard temperature, ordinary temperature, room temperature, and lukewarm as 20, 15–25, 1–30, and 30–40°C, respectively;
2. the term “in vacuum” indicating, unless otherwise specified, a pressure not exceeding 15 mm Hg;
3. the tabulation of the degree of coarseness or fineness of a powdered medicine; and
4. that in the monograph, if the upper limit of the content of an ingredient determined by assay is not specified but expressed simply as not less than a certain percentage, 101.0% should be understood as the upper limit.

The dosage form monograph in the JP has a section on methods of preparation that refers to the General Rules for Preparations, which gives definitions, methods of preparation, storage, and other information on 28 different dosage forms. The insoluble particulate matter test, included as a subsection in the section Injection, is currently under discussion among pharmacopoeia compilers for the purpose of establishing international harmonization.

The General Tests, Processes, and Apparatus section contains 60 test methods, such as fluorometry and electrometric titration, dissolution and disintegration tests, content uniformity, and a bacterial endotoxin test. Qualitative tests, reagents and test solutions, and standard solutions are also included. The Infrared Reference Spectra of 124 chemical entities are included in an appendix and will be updated in subsequent editions.

The JP monographs consist of the drug name, description, identification, rational values, and purity, as well as special tests if any, tests for preparation, and assay. No specifications are given in the JP 13 under monographs

for antibiotics, biologics, and radiopharmaceuticals. However, they may be found in Requirements for Antibiotic Products of Japan 1993 (formerly the Japanese Minimum Requirements of Antibiotic Products) and other corresponding compendia.

NONPHARMACOPOEIAL STANDARDS FOR PHARMACEUTICALS IN JAPAN

In addition to the *Pharmacopoeia of Japan*, there are several compendia, standards, and guides in which Japanese standards for pharmaceuticals are published. The following are standards determined for drugs under the provisions noted above, although the specifications and standards included in these compendia are mandatory. As presented above, some of the monographs in the following compendia are quoted in the JP:

- Requirements for Antibiotic Products of Japan 1993 (to be combined with the JP; antibiotic substance will be included in JP 14, due for release in 2001, and antibiotic products will be compiled in the Japanese Pharmaceutical Codex)
- Minimum Requirements for Biological Products
- Minimum Requirements for Blood Grouping Sera
- Radiopharmaceutical Standards

Several standards are published as advisements from the Pharmaceutical Affairs Bureau that set voluntary standards for various pharmaceuticals to ensure and improve their quality. Because the standards and specifications in these guides are voluntary, there is no overlap with the JP monographs.

- Japanese Pharmaceutical Codex, which contains monographs for 682 active ingredients and 175 pharmaceutical preparations (3)
- Japanese Pharmaceutical Excipients, which has 206 monographs for pharmaceutical excipient
- Standards for Crude Drugs
- Standards for Raw Materials for Clinical Diagnostics
- Guideline for Radiopharmaceuticals for In Vitro Diagnostics
- Insecticide Standards

IMPLICATIONS OF PHARMACOPOEIA IN THE REGULATORY PROCEDURES

Given that ensuring drug quality, efficacy, and consumer safety is a common objective for both

pharmacopoeial standards and drug quality regulation, the basic policy of one is not inconsistent in principle with that of the other. The JP Committee and regulatory agencies will enjoy a more harmonious relationship as they continue to develop closer contacts, both legal and otherwise. The JP secretariat belongs to the same Pharmaceutical and Medical Safety Bureau of the Ministry that oversees new drug approvals. Furthermore, several members of the JP Committee are also members of the NIHS, which shares some responsibility for reviewing new drug applications (NDAs) and for establishing guidelines for the technical requirements governing NDAs. These guidelines are updated whenever the JP is revised. History suggests that the revision of the JP and the revision of guidelines can be easily synchronized by the regulatory agencies that work closely together (4, 5).

Conformity of NDA Dossier with Pharmacopoeia

In the NDA procedures, specifications and methodologies should be based, as much as possible, on the entries in the JP, and careful attention must be given to the terminology used in the JP. In principle, reagents, test solutions, and testing apparatus used in proposed methodologies should be the same as those in the JP. When those used are not in the JP, their quality, formulas, schematics, and dimensions, etc. are to be entered on an attached sheet in accordance with the entries for such items in the JP. If the reference standards used are not specified in the JP or by the NIHS, details of the specifications and test methods must still be attached.

How Revisions of the JP Affect Drugs in a Market

As noted above, pharmacopoeial descriptions are mandatory for all drugs, regardless of whether they are listed in the JP or are in the process of being evaluated as a new drug. It follows, therefore, that revisions of the JP will greatly influence the standards for those pharmaceuticals. Revisions of the JP affects three areas of products already on the market:

1. In cases in which a new pharmacopoeial monograph is established, the NDA holder of a particular drug is required to apply for permission to change approved items, such as specifications and test methods, to ensure that the drug satisfies the pharmacopoeial monograph. A grace period of 1.5 years is allowed under current regulations for those products already

on the market to comply with new pharmacopoeial standards.

2. Whenever the standards in a monograph governing content, properties, testing, and purity limits for purity are revised, all related drug products currently in circulation must be changed to comply with the new standards in the JP. Manufacturers are responsible for ensuring that their products comply with the new standards. If these products do not comply, manufacturers are required to standardize the quality of their products to the level of the new standards within the grace period of 1.5 years.
3. When there are changes in the general notice, general rules for preparations, and specified test apparatus and test conditions in the General Tests, Processes, and Apparatus, previously approved drug products in some cases no longer conform to the specifications for which they were originally approved. For example, if the pH value of the medium in a disintegration test for a solid preparation changes, some products may yield different results under the new pH value requirement. In such a case, changing part of the formulation is recommended so that the product can comply with the specifications under the new test conditions. These situations occasionally present obstacles for later international harmonization of general test methods. It is necessary to overcome such obstacles by taking regulatory measures.

INTERNATIONAL HARMONIZATION

Role of Pharmacopoeia in the International Conference on Harmonization (ICH) Activities

The JP compilers are now part of an international harmonization effort with compilers of the *U.S. Pharmacopoeia* and the *European Pharmacopoeia*. Pharmacopoeias were taken up as an Expert Working Group (EWG) subject at an earlier stage of the ICH. However, pharmacopoeial harmonization should attempt to facilitate the international circulation of drugs and to improve drug quality rather than to simply facilitate the approval of new drugs. Furthermore, the Pharmacopoeial Discussion Group (PDG), which consists of European, U.S. and Japanese pharmacopoeia compilers and which was established in 1989 before the ICH, has held meetings periodically in parallel with the ICH to investigate a wide range of problems related to pharmacopoeia and to work on the harmonization of all

the monograph specifications and general test methods according to a long-term schedule. The PDG agreed with the ICH Steering Committee in that it felt it more appropriate to present a regular progress report at each ICH meeting from the PDG rather than to retain it as an EWG topic.

PDG Policy

To date, in its action plan for harmonization, the PDG has placed a high priority on the monographs of major excipients that can be used for a number of new drug products as well as on important general test methods. The PDG has established its general policy for harmonization, in which it is shown that the goal of harmonization is to bring the policies, standards, monograph specifications, analytical methods, and acceptance criteria of pharmacopoeias into agreement. Nonetheless, the PDG recognizes that such unity may not always be obtained. Where unity cannot be achieved, harmonization means agreement based on objective comparability and a clear statement of any differences. The goal, therefore, is harmony, not unison (6).

In harmonization of analytical methods, the ideal approach is to establish a single method that satisfies the criteria for validation of all pharmacopoeias. However, this is not always possible because of a number of unavoidable differences in the technical circumstances of each nation. When different tests or methods yield the same results, provisions have already been made in the three pharmacopoeias to allow for alternative methods. In such cases, alternative methods should be subjected to validation via a comparison with the standard analytical procedure.

It is undoubtedly impossible to achieve harmonization of quality for new drugs without harmonization of compendial standards and methodology. The PDG will continue to proceed with what it believes to be the correct approach to pharmacopoeial harmonization and to contribute to advancing effective harmonization for the quality of new drugs and products.

Mutual Agreement

In the licensing process, it is essential for each regulatory authority to recognize as equivalent those test procedures that have been harmonized and adopted as validated methods by the PDG. This concept is already included in the Japanese *Guidelines for Preparation of Section B of the Documents Accompanying New Drug Applications* as of September 1995; in its assertion that, "The analytical

procedures in the Japanese Pharmacopoeia and other compendia and those which are accepted through international harmonization are considered to be validated methods."

The ICH step 4 guidelines on specifications, Q6A, October 6, 1999, notes in the item concerning pharmacopoeia that:

References to certain procedures are found in pharmacopoeias in each region. Wherever they are appropriate, pharmacopoeial procedures should be utilized. Whereas differences in pharmacopoeial procedures and/or acceptance criteria have existed among the regions, a harmonized specification is possible only if the procedures and acceptance criteria defined are acceptable to regulatory authorities in all regions. The full utility of this guideline is dependent on the successful completion of harmonization of pharmacopoeial procedures for several attributes commonly considered in the specification for new drug substances or new drug products (7).

In this manner, key objectives of harmonization will be attained only when the PDG is able to achieve mutually agreeable standards and test methods, which provide the same conclusions when performed on the same specimens, even if they use different specifications, procedures, or reagents. We should continue to take necessary steps to deepen international cooperation and to obtain harmonized compendial standards and methodology, using the PDG as the forum for harmonization of drug quality.

CONCLUSION

This article describes the development of JP standards and their international harmonization and the relationship of the JP with drug regulatory procedures in Japan. It also notes that the JP has been playing a basic and leading role in ensuring and improving the quality of drugs in Japan. The pharmacopoeias of every country must constitute the basic technical foundation for the nation's drug quality standards and contribute to the promotion of public health by providing better pharmaceuticals to the public in the most efficient manner. The role of any pharmacopoeia is not only to define objectives for drug quality control based on the establishment of standards, test methods, and acceptance criteria, but also to provide means to implement the international harmonization of pharmaceutical regulation.

PHARMACOPOEIAL STANDARDS: THE *UNITED STATES PHARMACOPEIA* AND THE *NATIONAL FORMULARY*^a

Lee T. Grady

United States Pharmacopoeia, Rockville, Maryland, U.S.A.

INTRODUCTION

United States Pharmacopoeia (USP) and *National Formulary* (NF) standards and specifications relate to the quality, purity and strength, packaging, and labeling of medicines and related articles. The standards are public standards, and new and revised standards are published regularly. Official drug names and definitions are established, as well as tests or assay procedures that allow determination of compliance with the standards. But do the compendia reflect the state of pharmaceutical technology?

Resolutions adopted by the 1995 USP Convention are indicative of the interest and professional expertise shown by delegates. The General Committee of Revision elected by the Convention included categories of expertise critical to a modern pharmacopoeia. From the 138 standards-related members, 20 Division of Standards Development subcommittees were organized, along with a joint standards-information Nomenclature Committee, to carry out the continuous revision process.

The USP24-NF19 contains 3777 monographs and 164 general chapters (1). There are 543 new monographs, 504 in the USP and 39 in the NF. Continuous revision led to many new or improved requirements; 3941 individual revisions were processed through *Pharmacopoeial Forum* (PF) during the 5-year cycle. Obsolete material deleted during the preparation of this volume included 130 USP and 12 NF monographs, and 4 general chapters.

USP and Legal Recognition

Unlike all other pharmacopoeias, the USP and NF are not produced by government. The USP and NF are published by the U.S. Pharmacopoeial Convention, Inc., a voluntary,

not-for-profit institution that holds the public trust. Standards established in the USP and the NF are recognized by law and can be enforced by federal and state authorities. References to the USP and NF occur in numerous statutes regulating articles used in medical and pharmacy practice. The most significant is recognition of the official compendia in the Federal Food, Drug, and Cosmetic Act. These statutes usually empower the governmental agency to enforce the law using certain defined aspects of the compendia. Most commonly recognized are USP and NF standards for determining the identity, strength, quality, and purity of the articles and specifications for packaging and labeling. The Pure Food and Drug Law enacted by Congress in 1906 is a landmark in U.S. history. At that time, the USP-NF standards were given legal status, and the federal government was empowered, now resident in the FDA, to enforce USP requirements.

Congress reaffirmed this authority in 1938, and even the sweeping 1962 amendments did not alter this essential fact. During the 1995–2000 cycle, two statutes, the Dietary Supplements for Health and Education Act of 1994 (DSHEA) and the Food and Drug Administration Modernization Act of 1997 (FDAMA), extended the use of the USP and NF by amending the Federal Food, Drug, and Cosmetic Act. DSHEA specifically provided that a dietary supplement represented as conforming to the specifications of an official compendium will be deemed misbranded if it fails to do so. FDAMA requires pharmacists compounding drug products to use bulk drug substances that comply with the standards contained in a USP or NF monograph and the General Chapter on Pharmacy Compounding. Thus, the USP and NF are not published in response to any statute, but statutory recognition places burdens on the USP and NF with regard to clarity and precision of presentation.

Separate from recognition by drug laws of the various nations and use by registration or related authorities, pharmacopoeial requirements are used by commercial codes in that a request for a standardized article should be satisfied only by the article that meets those standards.

^aThroughout this article, the abbreviation USP, when used alone, signifies the U.S. Pharmacopoeial Convention, Inc. The abbreviation USP followed by Roman numerals signifies a particular revision of the *Pharmacopoeia*. The abbreviation USP-NF is used to signify the *U.S. Pharmacopoeia-National Formulary* and are taken to be USP24 and NF19, unless otherwise specified.

Pharmacopeias historically came before government regulations because rules or specifications had to be established before they could be supervised and enforced by the government. In recent decades, however, governments will not permit marketing of drugs unless these are duly registered or scrutinized for quality. Approval of new drugs is most widely appreciated, but international commerce also places such demands on a continuing basis. Compendial standards are a regular feature of all these governmental processes, usually by way of reference in one document or another.

Mission

The mission of the USP is to promote the public health through establishing and disseminating legally recognized standards of quality and information for the use of medicines and related articles by healthcare professionals, patients, and consumers.

U.S. Pharmacopeial Convention

The U.S. Pharmacopeial Convention (USPC) consists of delegates of nearly 400 organizations, including colleges of pharmacy and medicine, professional associations, and some federal agencies. The Convention arose from a national convention called by Dr. Lyman Spalding in 1817 to develop national drug standards for the polyglot, rapidly expanding developing nation. It met in 1820 and published that year the first U.S. Pharmacopeia (Fig. 1). The present revision is USP24 and NF19 (1). Between 1888 and 1975, the NF had been published separately by the American Pharmaceutical Association. It was acquired by the USPC

in 1975, along with the assets of the Drug Standards Laboratory that was a joint body funded by USP, the American Pharmaceutical Association, and the American Medical Association.

Essential aspects of compendial standards are intrinsic in the history and composition of the Convention. USP standards are meant to describe an acceptable article from the point of view of the physician–pharmacist–patient interfaces; and they are inherently time-of-use (that is, shelf life) requirements. Another outcome of this focus is that practical, medically significant aspects are dominant in assigning requirements and the limits therein. Compendial standards are always established from the viewpoints of the medical and pharmaceutical professions, which in the United States are represented by the USPC.

General Committee of Revision

The Quinquennial USP Convention in 1995 elected a Committee of Revision of 138 outstanding scientists and practitioners in the various disciplines relating to quality standards and drug information. Approximately 1000 prospective experts made themselves available when both standards and information programs are considered. These experts are volunteers from industry, academia, and government. Of these, 100 were experts in public standards. The other 38 accepted assignments in the Drug Information Division. Each elected standards-setting expert was assigned to one or more of 20 subcommittees (Table 1). The 20 subcommittee chairpersons and the chair of the Committee of Revision make up the Division of Standards Development Executive Committee. The entire Committee adopts “Rules and Procedures” (2, 3) by which

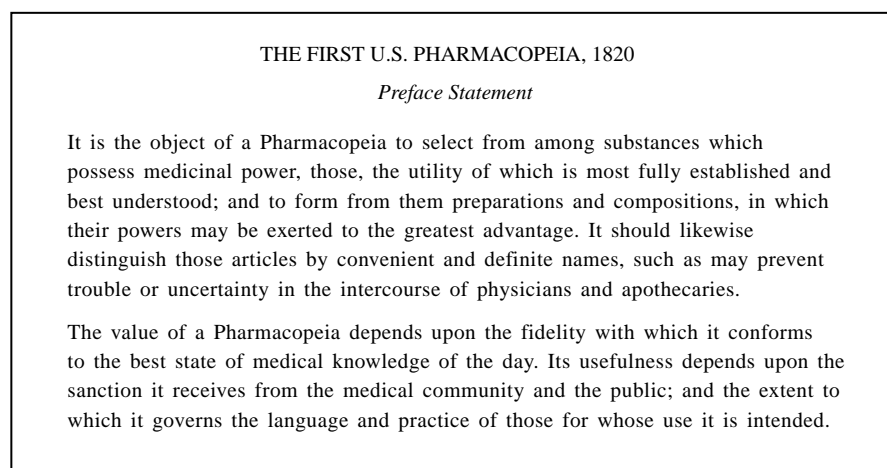

Fig. 1 *U.S. Pharmacopeia* Preface Statement, 1820.

Table 1 USP Subcommittees and chairs, 1995–2000

Subcommittee	Chairperson
Antibiotics	Henry S.I. Tan, Ph.D.
Biopolymers, Bioproducts, and Vaccines	Everett Flanigan, Ph.D.
Biotechnology and Gene Therapy	Robert L. Garnick, Ph.D.
Chemistry 1	Stanley L. Hem, Ph.D.
Chemistry 2	Dennis K.J. Gorecki, Ph.D.
Chemistry 3	Judy P. Boehlert, Ph.D.
Chemistry 4	Elliott T. Weisman
Chemistry 5	Edward G. Lovering, Ph.D.
Dissolution and Bioavailability	Thomas S. Foster, Pharm.D.
Excipients 1 (Monographs)	Zak T. Chowhan, Ph.D.
Excipients 2 (Methods)	Gregory E. Amidon, Ph.D.
General Chapters	Thomas P. Layloff, Ph.D.
Microbiology	Joseph E. Knapp, Ph.D.
Multisource Products Issues	James T. Stewart, Ph.D.
Natural Products	Paul Kucera, Ph.D.
Nonprescription Drugs and Nutritional Supplements	David B. Roll, Ph.D.
Packaging, Storage, and Distribution	Thomas Medwick, Ph.D.
Radiopharmaceuticals	Dennis P. Swanson, M.S., R.Ph.
Toxicity, Biocompatibility, and Cell Culture	Sharon J. Northup, Ph.D.
Water and Parenterals	James C. Boylan, Ph.D.

revision proceeds. A portion of the compendia is delegated to each subcommittee and, in agreement with its chairman, to each subcommittee member. Responsibilities are distributed for the more than 3700 monographs and the more than 160 general tests and information chapters. Every sentence in the USP and NF and every standard and its recognition are reexamined during each revision cycle. And every addition or change is given advance public notice and opportunity for comment.

The listing of subcommittee titles in Table 1 indicates the present scope of Committee interest and activity. The simple fact that a subcommittee has been created to deal with a subject area is a statement of its importance and implies that there are priorities in that area on the agenda of the Committee. As these interests change, the alterations are reflected in the USP periodical, *Pharmacopeial Forum*, discussed below. As outlined in the “Rules and Procedures” and noted above, any actions of subcommittees, or considered revisions to or adoptions of standards, are published for public evaluation and comment and are subject to mechanisms for appeal or request for postponement.

Council of Experts

The year 2000 USP Convention has adopted new structures and processes for setting public standards. The

Council of Experts replaces the historic General Committee of Revision. The resultant array of expert bodies and responsibilities is not available at this writing but may be found in *Pharmacopeial Forum* in 2000.

Headquarters

The USPC occupies several headquarters buildings complete with laboratories in Rockville, MD. It employs a staff of approximately 300 scientists, editors, and other employees to support the work of the Committee of Revision (Council of Experts). November 1998 saw the opening of the *Reference Standards Center*, a facility housing the *Reference Standards Laboratory* and the *Reference Standards Operations* unit. The USP Research and Development Laboratory remains in the 1989 headquarters building. As a publisher, the USPC performs its own phototypesetting, and its extensive in-house editing and production capability have been important to the timely publication of the standards. A modernization program is in progress to take advantage of the rapidly changing world of information-based products and technologies.

Financial Aspects

Independent standards setting is possible only because support for the program is undistorted by the impact of

standards on the governing bodies that ensure adequate funds. Funding is not dependent on those elements on which the standards impinge. Direct and narrow-based economic support from either government or industry would place standards setting in a less free or dampened environment. Opposed priorities or response to adverse impacts cannot be isolated from direct support. Financial independence is the component on which the USP program turns. Neither government nor industry gives direct supporting funds to the USPC for standards-setting activities or programs. Because these two are the major sources of funds for most nonprofit institutions, the corollary is that the USPC lacks immense reserves on which to draw and must be prudent in its expenditures. The USPC generates adequate income to meet its challenge as a public trust and to support growth and some ancillary programs noted here. Revenues for the USPC come from the following significant sources: sale of Reference Standards and publications. The committee members, advisory panelists, trustees, and convention delegates serve without monetary compensation, out of their sense of public service and professional responsibility.

PROGRAMS AND PUBLICATIONS

Pharmacopeial Forum and Continuous Revision

Pharmacopeial Forum, with the ability to publish official supplements twice yearly, has brought to fruition a dominant feature of the USP continuous revision. Only in this way can the USP keep pace with the progress of pharmaceutical technology and thereby escape the doom of continuing obsolescence. As the art of pharmacy, whether in design, manufacturing, or testing, became ever more the science of pharmacy, the compendia kept pace. An electronic, web-based product became available in 2000.

The bimonthly *Pharmacopeial Forum*, called “the journal of drug standards development and official compendia revision,” presents proposed new or revised USP and NF standards for public review and comment. *Pharmacopeial Forum* enables the reviewer to see at a glance both the text that is proposed for deletion and the text that is proposed for addition or modification. *Pharmacopeial Forum* is offered by subscription to all interested parties. Thus, interested scientists and practitioners from the general public other than the Committee of Revision and its advisory panels have access to the latest proposed revisions in the official standards and tests and can readily transmit their comments, suggestions, and data to USP headquarters for consideration by the Revision Committee.

In addition to presenting proposals recommended by the Committee of Revision in a section entitled “In-process Revision,” the *Pharmacopeial Forum* contains several other sections. The “Headquarters Column” gives information on publication deadlines, news, or statements of the Pharmacopeial Convention and the Committee of Revision, summaries of issues discussed by the Drug Standards Division Executive Committee, and various tabulations or lists that aid in keeping track of the multifaceted revision program. A section called “Stimuli to the Revision Process” publishes reports or statements of authoritative committees, scientific articles relevant to compendial issues, general commentaries by interested parties, and collations of comments received in response to policy initiatives. A recent addition is a section on International Harmonization.

Pharmacopeial Forum is intended to promote public comment at the earliest possible stage in standards development. Industry is the largest single participant in that activity. This periodical has been shown to stimulate comment and therefore can be credited with increasing the pace of revision. What comes to mind is an analogy of USP revision to a thixotropic gel—as the pressure is increased, so is the flow. This periodical operates in tandem with the program of Open Conferences to ensure vigorous participation in standards setting.

Related Publications

Efforts are under way to make the USP-NF more useful worldwide. Incorporation of monographs for multivitamin products, biotechnology-derived products, veterinary drugs, and botanicals and other dietary supplements help. The *USAN* and *USP Dictionary of Drug Names* has wide international applicability, thereby making it a repository of International Names & Nomenclature (INN) and British Adopted Names (BAN), as well as U.S. Adopted Names (USAN). *Pharmacopeial Forum* now contains announcements of proposals from the *Japanese Pharmacopoeia* and *European Pharmacopoeia* for revision of standards for international harmonization.

Open Conferences and Meetings

Consistent with the USP policy of emphasis on public participation in standards setting, open conferences and meetings are held to allow interactive examination of selected topics. Twenty-five of these conferences were held between 1980 and 1999, with an average attendance of approximately 150. Roundtable format is used to get maximum participation policy initiatives as well as proposed standards revisions on the table.

International Training and Outreach Programs

USP standards and information are recognized and used by many countries (19, 21), and the USP seeks to encourage, enhance, and facilitate their use. Examples of USP programs to train non-U.S. scientists and to seek their advice on how USP programs and products can be made more useful to other countries include sponsorship of visiting scientists and scholars, supporting doctoral and postdoctoral fellowships, cosponsorship of meetings and conferences, and formation of the International Health Advisory Panel.

Visiting Scientists and Scholars Program

Since 1990, the USP has substantially expanded its program for visiting scientists and scholars. Originally conceived as a program to train scientists from pharmacopoeias and official control laboratories, the program has been expanded to include scientists who spend up to 4 months in the USP Drug Research and Testing Laboratory or in the secretariat for the USP-NF within the standards development divisions to gain experience in laboratory techniques or pharmacopoeial revision procedures, as well as scholars from regulatory agencies and drug information centers around the world interested in the work of the information-development divisions in compiling and updating the USP DI database and USP information products.

Since 1990, the USP has hosted visiting scientists and scholars from China (13), Indonesia (2), Argentina (5), Nigeria (3), Poland (2), Romania (2), Turkey (2), Russia (2), and 1 each from Germany, Japan, Thailand, Korea, Kenya, Italy, and Kyrgyzstan.

Fellowship Program

The Fellowship Program is directed primarily at pre- and postdoctoral U.S. students. The USP has awarded 160 fellowships since 1981. The USP Fellowship Program also grants awards to non-U.S. students and postdoctoral fellows at U.S. universities and at universities outside the United States, provided the criteria for award can be satisfied. Currently the USP grants 10 fellowships annually: 6 in drug standards and 4 in drug information. Stipends are \$15,000 per year, and a fellow may compete for support for a second year. Eligibility criteria require, among other factors, that the fellowship application be signed by a member of the USP Committee of Revision, an advisory panel, or the board of trustees at the institution where the applicant is studying. Applications are reviewed for technical merit and relevance to USP standards and

information programs by committees of members of the Committee of Revision from the standards and information divisions.

Asian edition

In response to globalization and increasing use of the USP-NF abroad and to the foreign exchange picture, USP23-NF18 and USP24-NF19 both were published in Mumbai (Bombay) India simultaneous with the main publication in the United States.

Spanish language version of the USP-NF

The Spanish language edition of USP 23-NF 18 was published in 1995 as a DOS-based electronic product. In 1998, the product was converted to a Windows-based electronic product. Work on the translation of USP-NF text began in 1993 with the exploration of machine translation software suitable for use in the translation of the characteristic text of the USP-NF. The software selected was ENG-SPAN-AMSM from the Pan American Health Organization. This was fortified by a microdictionary and software macros specific to the compendia. Since the initial release in 1995, the USP has released Supplements for the Spanish language edition concurrent with the release of the English language Supplements. The database continues to be kept abreast of revisions to the USP and NF, but it was not marketed after 1998.

NATURE OF COMPENDIAL STANDARDS

Scope

The first USP begins, "It is the object of a Pharmacopeia to select from among substances H those, the utility of which is most fully established and best understood" (Fig. 1). Subsequent USP Conventions have broadened that to encompass all safe and effective medicines and some related articles. Recognition by the USP is not based on the identity of the manufacturer, the environment in which used, or the existence of borders or restrictions on commerce. Articles are adopted into the USP and receive standards scientifically appropriate to the articles, irrespective of whether the article is over-the-counter or prescription only and whether the article is used at home, in the practitioner's facility, in the hospital, or even in a licensed facility. The same modern standards are applied, and the public is offered the same parameters of strength, quality, and purity. Also, the same opportunities exist for analytical challenge or regulatory compliance.

USP and NF Standards Are Public Standards

This distinction was expressed well by the late C.A. Johnson of the *British Pharmacopoeia* (4):

The first point to be underlined is that the pharmacopoeia provides a collection of publicly available standards that are open for inspection and challenge by all—a fundamental right in any civilized society. The standards are established only after wide public consultation—a procedure that deserves to be maintained and supported. Because of the public availability of standards for medicines any authority or, indeed, any individual, may cause a random sample of a medicine on the market to be challenged.

As noted previously, compendial standards arose from the professions on behalf of the public. There are no attempts at regulation by the USP of the daily application of pharmaceutical technology. USP standards are not to be confused with such concepts as the “product description.” As addressed below, compendial standards are not manufacturing directions as such and do not constitute the manufacturers’ release criteria. They define the acceptable article as and when used.

Functions and Responsibilities of Compendial Standards (5)

What are the functions of USP standards? First, remember the nature of any standard. A standard is a rule, a principle of orderliness, that implies: 1) an element of agreement or acquiescence of most concerned, 2) some authority, and 3) some benefit to be gained by all concerned. To obtain this agreement in a reasonably democratic way, as opposed by way of authoritarian edict, there must be an element of compromise. However, one fact cannot be ignored: adoption of one rule implies rejection of alternative rules. In a real sense, this is loss of freedom of choice. The question comes—what do we get in trade? Why standardize? Why go through the occasionally wrenching experience of compromise? We get orderliness instead of chaos, and where there is orderliness, and only then, we get predictability. The essence of a USP standard is predictable drug product quality. The benefits of that predictability are settled on all concerned: the public, the professionals, the manufacturers of quality products. Without predictability in use, drugs would not have won the fullness of their position in society today. Physical and chemical tests and specifications are given for measurable quality parameters. Official drug names and definitions are established, which give a common vocabulary and a clear

understanding to communications within and among the professions.

Why do we persist in saying “public” standards? Because compendial standards, proposed and adopted, are published and circulated in public. The standards state to the public, manufacturers, and professions what constitutes predictable drug product quality from lot to lot and from manufacturer to manufacturer. The parameters of that predictability are published for all to see, for all to discuss, for all to grant their element of agreement, or for that matter, for all to contest publicly. Other agreements and other compromises, however reasonable and neatly filed away and for whatever reason not available, cannot fill that simple, rightful need of public information.

Codifying an element of predictability is not the only function of public standards. The USP-NF standards are enforceable by law, and are enforced strongly. This is the second function of USP standards: providing a basis for active protection of the public from unacceptable articles, not merely establishing ideals to be ignored when convenient. The USP and NF give detailed tests or assay procedures that allow determination of compliance with the standards; indeed, to call for a quality level without supplying a proof test would be unenforceable. Third, the quality manufacturer knows that other manufacturers of the same article must pass muster as well. Two less obvious purposes should be noted. The participants in the revision process also focus timely attention of industry and government on important problems or new technologies. Also, to a large measure the compendia define the state of the art of pharmaceutical analysis and therefore have impact as well on general drug registration and nonofficial articles both here and abroad.

Beyond defining acceptable articles, what are the responsibilities of USP and NF standards? The USP must strike a balance between the right of all concerned parties to act independently and efficiently and the need to preserve the rights of the patient to safety and quality. The USP and NF are responsible first to the public. These compendia can encourage the experts to make the quality judgments that the public cannot. The USP and NF are responsible to the practitioners of medicine and pharmacy who understand and are bound by the need for standards. The USP and NF are responsible to put forth standards that are meaningful to government and that can be enforced. The USP and NF are responsible to industry to put forth standards that are meaningful, practical, and affordable. The goal of the USP and NF is to set standards that are equal to the need, that can be enforced, that can be met by capable manufacturers, and that, at least for the moment, satisfy pharmaceutical scientists and practitioners.

Drug product quality in the United States is more reliable, more predictable than other aspects of the system of healthcare delivery as a whole. Adding tests or tightening specifications at the manufacturer level that does not help patients or professionals derive further benefits from drugs does little except increase patient or taxpayer drug bills. There is something to be said for knowing when to stop. We must be able to recognize diminishing return!

Drug product quality stands out in sharpest detail and is most highly visible to those of us in this technical community. Our concerns are those of the specialist for his or her field. In contrast, consider the heavy mist through which we gaze at problems of predictable therapy—not of differences in predictability resulting from variations in lots or brands, but of differences in pharmacogenetics; dietary habits such as preferences in beverages or entrees; metabolism as a function of disease, age, or sex; or, on a larger scale, failures in patient compliance or drug interactions.

General Approaches to Standards (5)

We can recognize three distinct but interdependent, effective standards: 1) USP-NF standards, 2) current good manufacturing practices, and 3) in-house quality assurance or process validation protocols. The three programs are different but have the same objective: drug product quality. The official standards are developed to be meaningful in this multiple context. In recent years, a similar array has occurred in most developed nations, and this is rightfully seen as a measure of success.

Currently, public standards tend to be performance rather than design standards. To illustrate: Are only automobile exhaust emissions measured as proof of success in reducing pollution or is an “official engine,” complete with engineering drawings, promulgated? In performance tests, desired attributes are tested for postmanufacture. This is end-product testing. These answer the fundamental question: How did it turn out? Older monographs, with prescription-like formulas but few tests, were essentially design standards. Only a few such appear in USP24. The resurgence of pharmacy dispensing now will result in more design-type standards. The trend toward performance tests has been the case in all standards except, notably, plumbing codes. One can imagine the difficulty of converting a visit of the plumbing inspector from an examination of allowable joints, angles, and materials to an experiment in which recovery of a test specimen of a hamburger slurry is a pass/fail criterion. Pharmaceutical technology now takes this one step further

and recasts the design standard as a “validated process” when the demonstration by end-product testing can lead to sufficient confidence in both the design and the process of carrying out the design.

Design standards intrinsically must be more detailed, more complex, more arbitrary, and more authoritarian than performance standards. Specific formulas can be specified by USP-NF, as can methods of compounding or processes of manufacture if necessary. However, end-product testing is believed by most pharmaceutical scientists to be adequate public standardization. That is what the patient does—end product testing!

USP-NF standards are established with the specific intent of serving as instruments of enforcement. Because these standards may be the common ground in a legal contest, the compendia publish both the experimental details and the limits within which the results must fall. Pass or fail—not how well, or by how much. Is it or is it not an acceptable article? Claims that a product “exceeds” USP specifications distort standards concepts. The compendial standard is that which any specimen of that article must meet at any time during its valid life. Although not a criterion aimed at use as a release standard, it is clearly the ultimate element in assigning expiration dates. It is the door at the end of a long hallway, not an immediate opening to the marketplace.

Limitations of Standards

Let us start with a truism. Quality is built into a product; it cannot be tested into it. It is also true that failure to build quality into a product can be tested for, as can variations from a good norm. The last century coped with a problem and a paradox: a redefinition of what was good and, most significantly, what was good enough (6). In this way, statistical quality control developed. We accepted the idea that even if absolute precision in manufacturing were possible (and it is not), it would be superfluous. When we strive for product uniformity, we still remember that quality will vary, so that what we really aim for is standardization of quality within limits. That is why “quality” requires control. The object of control is to enable us to do what we want to do, with economic limits (6).

We accept the inevitability of imperfection, thus we must accept the inevitable need for quality standards. Thus must we also accept the imperfection of those same quality standards. Compendial standards must be what can be done; failure to publish a standard because it is imperfect can be failure to serve the public. I submit that a willingness to move forward in the face of imperfections is

consistent with the second maxim stated by Descartes (7), which applies to any uncertain situation, to move resolutely and unswervingly in the most promising direction.

TECHNICAL FEATURES OF COMPENDIAL STANDARDS

Pharmacopoeias always have been as much statements of current technology as of current therapy. Examination of an older pharmacopoeia from any time or place gives a fair measure of the contemporary drugs available, therapeutic strategies, and medical knowledge. No less does such examination give a fair measure of the contemporary pharmaceutical technology. Pharmacopoeial standards arise from the contemporary, controlling concepts of what constitutes good quality and, further, how one achieves or demonstrates that quality. However, selection requirements can come only from processes and equipment in general use. Available technology determines what is to be required or standardized, just as it determines what can be made.

A rough correlation existed between pharmacopoeias and pharmaceutical technology. At least that was so until the modern drug era, when new drug discoveries proceeded at rates that, in one generation, rendered many pharmacopoeias obsolete, especially those that could not revise as frequently as is done by the USP. Increased international trade and acceptance undercut the need for large numbers of national pharmacopoeias. Technology forged ahead on many fronts in manufacturing processes and equipment, dosage form design, new kinds of excipients, and new analytical capabilities. Only a few pharmacopoeias continue to publish specifications of practical import consistent with the state of pharmaceutical technology, and these are primarily regional or international in scope. Different adaptations to rapidly changing therapy and technology account for some of the unevenness in and among pharmacopoeias and a consequent need for harmonization. We report here on current compendial specifications, what they are, by whom and where they are established, and how and why they are created.

Official Names

Pharmacopoeias are an accumulation of responses to problems in medicine, pharmacy, or pharmaceutical technology as these presented themselves over the years, even over centuries. From the beginning of pharmacopoeias, a fundamental function has been the establishment

of names “such as may prevent trouble or uncertainty in the intercourse of physicians and apothecaries” (Fig. 1). Different things should have different names; that is a fundamental principle of compendial standards. This applies to dosage forms as well as to molecules. This deeply rooted function seldom gets much attention until someone wants to change something. A recent case is the desire to change the capability of consumers to identify the ingredients of products through product labeling of all inactive ingredients. The need for concise, unambiguous names for these ingredients as well is inescapable of notice.

A cooperative effort since 1961 between the American Medical Association and the USPC was augmented in 1964 by the addition of the American Pharmaceutical Association, then the publisher of the NF, to form what has been known since as the U.S. Adopted Names (USAN) Council. The U.S. Food and Drug Administration (FDA) was invited to join the Council in 1967, and the FDA refers to USAN names in its regulations. The Council consists of persons conversant with the needs and problems of naming drugs and an appeals body. The names determined by the Council are incorporated, along with other names for drugs (including public, proprietary, chemical, and code-designated names), in an annual book, *USAN and the USP Dictionary of Drug Names*, published by the USPC.

Method and Specification Selection

The selection of USP methods and specifications can be concluded to be practical consequences of what has been successful in detecting drug product quality variability and what can ensure demonstration that variations in quality remain within acceptable limits. USP methods are selected for their fitness for use for that monograph application, just as USP Reference Standards are adopted on the basis of suitability for intended use in that monograph.

Tests and specifications, and reagents as such, were introduced into the USP in the 1890s. The first truly instrumental determination used was the Wild polaris-trobometer for natural oils in 1890. Trends were established in USP XV (1955) toward decreased monograph prescriptions, or design standards, and, separately, toward the increasing range of General Tests. The USP now has more than 160 general chapters. There are few analytical methods used in modern pharmaceutical analysis that are not used by the compendia.

An interesting historical change in the orientation of the USP is implicit in this discussion. Until the age of instrumentation, there was an expectation that compendial

methods could be performed in a community pharmacy. What became possible decided where it could be done, and the focus moved out of the pharmacy and into the central analytical laboratory.

Tremendous changes in the selection of compendial methods have occurred in recent decades. Classic physical and chemical measurements had long been established as objective criteria for quality assurance and for compliance testing, but these had significant limitations for dosage forms, both as assays and as limit tests. As recent decades have witnessed a torrent of instrumental developments, it should be no surprise that the compendia have experienced a resultant flood of applications that use those instrumental methods popular in the industry. The previous limiting factors, the availability of instruments their and reliability (or certainty of repair) ceased to be a problem even before the revolution in microelectronics.

The USP placed emphasis in the last 20 years on stability-consciousness and impurity-consciousness in preparing monographs. See 1086, *Impurities in Official Articles* (1). These major trends explain the prominence of chromatography. It is obvious that the major portion of recent revision revolves around chromatography: high-pressure liquid chromatography (HPLC), gas-liquid chromatography (GLC), and thin-layer chromatography (TLC) for identity tests and reference standard evaluation; HPLC, GLC, and TLC for purity or limit tests; and HPLC and GLC for assays. Much effort is spent in evaluating chromatographic systems and identifying System Suitability Tests (see discussion below) to make these methods more reliable. The amazing speed with which HPLC was adopted as mature scientific measurement is nowhere more evident than in drug analysis and, therefore, in the USP. The USP 24/NF 19 contains 1800 HPLC/GLC and 740 TLC initial references. Because of cross-referencing of substance methods in dosage form monographs, the total number of chromatography-based requirements is much, much higher.

To a large extent, modern separation science has solved a previous significant problem in compendial method selection, that of interfering substances. The USP does not lock all manufacturers into the same formulation and manufacturing procedure, and the USP allows considerable freedom as long as the substances added in dosage forms do not interfere, which these must not do (8), with the official tests and assays. Because the manufacturer can change the formula or introduce new products, it is unreasonable to assume that the USP would have tested every conceived and about-to-be conceived product. Thus, in exchange for the freedom of formulating, the individual manufacturers have the responsibility of keeping up with

proposals in the *Pharmacopeial Forum* and assessing the applicability of proposed methods to their specific existing products and their contemplated new products, i.e., validation for their formulations. Separation science now available makes it likely that a method workable for all can be identified.

Automated Methods

In considering the introduction of new test methods, it has been necessary for the USP to recognize the appropriateness of automating compendial assays and tests. The Committee of Revision prefers to adopt automatable procedures, especially for multiple-unit specimens such as those arising from dissolution or content uniformity requirements. Thus, since the publication of the USP XVIII in 1970, the General Notices to the USP has included automated procedures in discussions on the use of suitable alternative methods. The General Notices to the USP24 state (9):

Automated procedures employing the same basic chemistry as those assay and test procedures given in the monograph are recognized as being equivalent in their suitability for determining compliance. Compliance may be shown also by the use of alternative methods, chosen for advantages in accuracy, sensitivity, precision, selectivity, or adaptability to automation or computerized data reduction or in other special circumstances. Since Pharmacopeial standards and procedures are interrelated, only the result obtained by the procedure given in this Pharmacopeia is conclusive where a difference appears or in the event of dispute.

Thus, the USP states explicitly what is to be done and in what sequence but not by whom or by what.

Stability

Monographs do not include a specific section that deals directly with this major aspect of drug product quality, primarily because stability is related to a number of factors including chemical structure, formulation ingredients and processing, bioburden, packaging materials and storage, repackaging, and geography. Concern for stability is manifest in the Pharmacopeia in at least seven ways: 1) the general requirement for expiration dates, 2) monograph packaging and storage requirements, 3) standards for packaging materials and containers, 4) standards for repackaging and storage, 5) limit tests for decomposition products, 6) stability-indicating tests or assays, and 7) the informational General Chapter, "Stability Considerations

in Dispensing Practice.” Underlying these standards are standard definitions of storage conditions. An emerging establishment of requirements for Labile preparations will add an eighth stability-resultant category. New informational chapters are likely to expand this list. Stability is not causal—it is the effect of choices during formulation development, packaging, and storage instructions.

Test Results, Statistics, and Standards (10)

Confusion of compendial standards with release tests and with statistical sampling plans occasionally occurs. Interpretation of results from official tests and assays requires an understanding of the nature and style of compendial standards. Tests and assays given in the USP prescribe operation on a single specimen; that is, the singlet determination. This is the minimum sample on which the attributes of a compendial article should be measured. Some tests, such as those for dissolution and uniformity of dosage units, require multiple-dosage units in conjunction with a decision scheme. It is to be understood that these tests, albeit using a number of dosage units, are in fact the singlet determinations of those particular attributes of the specimen. These quantities should not be confused with statistical sampling plans. The compendial procedures demonstrate compliance of the attributes of an article with compendial standards only for that specimen (of one or more dosage units) that is subjected to analysis. Repeats, replications, and extrapolation of results to larger populations are neither specified nor proscribed by the compendia; such decisions are dependent on the objectives of the testing.

Commercial or regulatory compliance testing, or manufacturer’s release testing, may or may not require examination of additional specimens, in accordance with predetermined guidelines or sampling strategies. Moreover, a statistical plan may be necessary to relate the shelf life of the product, test results, and release specifications to the ultimate compendial specifications.

System Suitability Tests

System Suitability Tests are now characteristic of USP methods (10, 11). They are based on the concept proposed by this author in early 1971 that the instrument, reagents, packings, conditions, procedural details, detectors, electronic accessories, and even the analyst constitute a single system that is therefore amenable to an overall test of system function. Reliable chromatographic performance, for example, may require specifications for resolution,

column efficiency, peak tailing, precision of replications, or extremes of conditions. Such tests obviate the necessity of specifying a multitude of instrumental settings, model numbers, names of manufacturers, packings and lot numbers, and other physical-chemical and engineering characteristics. Also avoided is the distribution of official lots of chromatographic packings through the compendial headquarters. System suitability tests were first made official in the USP XIX and have come into general application.

New Technology and USP Contents

During the revision cycle, the USP introduced a Web site that contains up-to-date information about the USP and its program as well as ordering instructions. The USP home page is located at www.usp.org.

Law and regulations ensure the adequacy of the premises, practices, and documentation of the manufacture of drug substances and preparations expected to result in articles that comply with pharmacopoeial standards. It was the practice of previous USP revisions to publish and update the FDA Good Manufacturing Practices (GMPs) in a general information chapter *Good Manufacturing Practices* (1077). This was perceived to be a service to those in manufacturing establishments and pharmacists. Rapid expansion of the Internet and almost universal establishment of Web sites by all institutions abrogates, in general, the perceived need that necessitates this service. Therefore, this revision cycle culminated in the deletion of federal and other texts now reliably available at no cost through the new technology. Federal documents can be found on the U.S. Food and Drug Administration Web site at www.fda.gov. Along with *Good Manufacturing Practices* (1077), two other general information chapters based on federal regulations are deleted: *Federal Food Drug and Cosmetic Act Requirements Relating to Drugs for Human Use* (1076) and the frequently revised *Controlled Substance Act* (1071).

Drug Release

Nowhere have the value and failures (and political pressure) of pharmaceutical technology been more apparent than in the complex of processes that amount to release of active ingredient from its pharmaceutical presentation. A major concern, now a generation old, was reliable release of drug from solid oral dosage forms (11). The USP and NF each introduced dissolution tests in six monographs in 1970. For some drugs, absorption is dissolution-rate controlled, reduction in bioavailability

results. This is precisely a reduction in strength and has no additional resulting in medical significance. The problem arises when two formulations of such a drug are compared where dissolution rates are substantially different—this is known as bioinequivalence. This led to much commercial mischief and distortion of scientific facts to achieve protection of existing products from competition. Some scientists emphasized drug chemical properties as the central factor—particle size or solubility, for example. Others pointed to the inactive ingredients used in the processing of compressed tablets—lubricants and disintegrants, for example. Or there was emphasis on the process itself, as in overcompression. Pragmatists noted the continued use of hydrophobic tablet coatings—shellac, for example.

A drug release test, dissolution, was a satisfactory standard every time there was a problem of any practical consequence. Of equal significance was the recognition of the strength of dissolution testing as a tool for quality control. Thus, equivalence in dissolution behavior was sought in light of both bioavailability and quality control considerations. The USP 24 has more than 600 monographs for tablets and capsules: 500 have an official dissolution requirement; 100 others have a different performance test considered appropriate for acceptable drug product quality.

For USP tablet and capsule monographs, we know of none where two articles, fully in conformance, have clinically significant inequivalence. Experience has demonstrated that when a medically significant difference in bioavailability has been found among supposedly identical articles, a dissolution test has been efficacious in discriminating among these articles. Because the USP sets forth attributes of an acceptable article, such a discriminating test is satisfactory because the dissolution standard can exclude definitively any unacceptable article. Therefore, no compendial requirements for animal or human tests of bioavailability were necessary. The practical problem has been the obverse; that is, dissolution tests are so discriminating of formulation factors that may only sometimes affect bioavailability not uncommon for a clinically acceptable article to perform poorly in a typical dissolution test. In such cases, the Committee of Revision has been mindful to include as many acceptable articles as possible but, at the same time, to exclude dissolution specifications so generous as to raise reasonable scientific concern for bioinequivalence.

There is no known medically significant bioinequivalence problem with articles of which 75% is dissolved in water at 37°C for 45 minutes with the use of either official apparatus at usual speed. A majority of monographs have

that as the requirement, and this is called “First Case” in the *Pharmacopoeial Forum*. Other articles for which there are no known or likely medically significant bioavailability problems have required some adjustment of medium or apparatus.

Details of tests and specifications can be found in the USP. For ordinary tablets and capsules, the apparatus used (basket and paddle) affords low levels of agitation appropriate for challenging drug products with a significant potential for diminished physiologic availability. Similarly, only the most discriminating solvents are selected. See 1088, *In Vitro and In Vivo Evaluation of Dosage Forms*. Extended-release formulations present different standards problems. Pharmacologically sound judgment that a drug is acceptable as an extended-release product obviates the necessarily conservative choice of apparatus and conditions applied to ordinary articles. Either the drug does not have a significant absorption problem or its metabolites are active, in which case a higher agitation apparatus may be necessary. A new apparatus is presently under consideration to handle those cases in which the current apparatus is unworkable.

Dietary Supplements

Dietary supplements are now covered by federal legislation (see DSHEA under Legal Status of the Official Compendia, above). They are a rapidly growing aspect of consumer choice. The USP and NF made great progress in this field in the years after the 1995 Convention. The Convention debated vigorously on the proper placement in the compendia, if any, necessitated by the resurgence in the United States of the use of botanicals, amino acids, and other substances. These had fallen into disuse earlier in the century (see 1995–2000 *Resolutions* in the *Proceedings*). The feasibility of standards was established quickly, and there developed a broad support for USP-NF monographs. The area of information for consumers and practitioners has been the more contentious. The first task was to identify the most widely used botanicals having no counteracting safety concerns.

Dietary supplements are on a different legal footing from drugs, being regulated as foods or under food statutes. In contrast to drugs, supplements are not required to comply with compendial requirements unless labeled to be the official article, in which case it is necessary to use compendial methods. Labels that specify USP or NF in supplements are gaining momentum. Although there is extensive analytical experience with vitamins and minerals, problems in the analysis of botanicals are likely to arise because a tradition of testing is not widespread.

Very complex mixtures are the rule, and there is uncertainty as to the critical components.

In response to a resolution adopted at the USPC's 1995 Quinquennial Meeting, the Committee of Revision addressed issues concerning natural products of plant origin used as dietary supplements. The Subcommittee on Natural Products, assisted by the Advisory Panel on Analytical Methods for Identification and Characterization of Natural Products, set priorities for 21 botanicals for standards development. The criteria underlying the selection included absence of safety risk; extent of use as reported by trade sources; positive assessment by recognized pharmacognosists, usually on a presumption of beneficial pharmacological action and history of use in traditional medicine; and the ability of the article to be able to meet typical USP-NF monograph requirements.

A new admission policy addresses botanicals used as dietary supplements recommended for their official adoption by the USP Committee of Revision. When the FDA has approved a use or a USP DID advisory panel has accepted a use, it is to the USP. If neither condition is met, and there is no safety concern, the article is admitted into the NF. If there is a safety concern for an article, then no NF monograph is published, and USP DID will publish a monograph that is negative on the use of this article. The first official monograph resulting from the 1995 USPC appeared in the Seventh Supplement to the USP in 1997. That was Ginger, USP. A total of 18 monographs were published through the First Supplement to the USP24-NF19.

Compounding Pharmacy Monographs

A corresponding resurgence in compounding practice has arisen from the unavailability of strengths or forms suitable for special populations, especially pediatric patients, and for short-life preparations such as a buffered, diluted solution of sodium hydrochlorite. The Advisory Panel on Pharmacy Compounding was installed. Pharmacists from this Panel advised the Subcommittee on Packaging, Storage, and Distribution where most scientific questions on prescription stability, packaging, and storage could best be resolved.

The USP laboratory evaluated all the monographs, and its findings were published in *PF*. Ten official monographs were published through the USP24-NF19 Second Supplement. The International Association of Compounding Pharmacists is playing a key role in selecting among the many known formulas to identify those of more medical merit and wider usage. Additional monographs are expected to appear in subsequent supplements. If

a commercial article is available, no compounding USP monograph is needed. As noted above (see Legal Status of the Official Compendia), recent legislation supports and guides pharmacy compounding.

Excipients

Standards for more than 350 excipients are published by the USPC, primarily in the NF (approximate 270 versus 80 in the USP). Before 1975, the USP and NF were published by different organizations; each had monographs for drug substances, dosage forms, and excipients. The USP adopted the medically best, and the NF adopted those widely used. With the 1975 merger, it was decided to publish the so-called inactive ingredients in the NF and, in addition, that both the USP and NF publications would be bound together in a single volume and have joint supplements.

The advance of pharmaceutical technology ever forces forward new or refined excipients, some with heretofore unexploited properties. Polymers are a case in point and have been central to many of the technological advances of recent years. New and different challenges for compendial standards are offered by materials used in new wave formulations. Modern analytical chemistry allows rather thorough evaluation of materials.

Excipients were a major, and the initial, component of programs for international harmonization. The USP focuses on functionality tests, such as for that compressibility. These are available for many excipients. Why incorporate functionality requirements into the NF that assess parameters that are critical to a minority of purchasers, thus restricting the channels of commerce and probably raising everyone's costs? If viscosity range or degree of crystallinity is critical to one formulation, isn't that the problem for that formulation? One solution would be to adopt a standard test but to require that the product labeling state the specification to be applied to the contents. The product label would state the definitive parameter(s). The NF is satisfied at present with an array of standards of identity, purity, assay, moisture, packaging, storage and labeling, and so forth that supports the name and labeling of materials.

Reference Standards

In support of its program for public standards for drugs, the USPC supplies the Reference Standards required by the monograph standards, tests, and assays of both the USP and the NF. Biologic assays in the USP were the first to require use of reference materials. Authoritative sources of

these were needed, and the first were adopted in 1926. As an index of the growth of analytical science, 45 were needed in 1950 for the USP and NF and 438 in 1980. As of 2000, there are 1400.

One cannot fail to note the vast expansion of the collection in the last few decades. Surely this was not fueled by additional biologic assays. Underlying the initial growth phase was the widespread utilization of spectrophotometry for identification and assay. Separation science was the second phase in pharmaceutical industry control laboratories. As a corollary, USP and NF method selection moved in the same direction. Spectrophotometric identity tests and assays are more reliable, especially for compliance testing, when performed in the relative mode, which uses a reference standard, rather than the absolute mode, which is the norm in titrimetry. There is some residual difference of opinion in other countries on this point, but that is rendered moot by the widespread adoption of separation science by the pharmaceutical industry and, thus, by the compendia. It is a characteristic of chromatographic methods that a reference standard be required, sometimes more than one for a procedure. The accumulation of modern tests and assays results in 5 to 10 uses for many reference standards.

Two critical features of this program should be remembered: all USP Reference Standards are subjected to collaborative testing to generate a purity profile and then must be approved by the USP Reference Standards Committee, which is composed of members from the Division of Standards Development Executive Committee. Three or more laboratories test each one. For this purpose, reference standard purity is defined as known composition with respect to intended use. Adoption of a chemical batch demands a known purity profile, which is obtained by meaningful experiments. Although the USP or NF monograph requirements are met, testing usually ranges beyond the monograph tests to construct a purity profile, particularly in the accumulation of more extensive chromatographic characterization. In contrast to the highly purified synthetic organic medicinals, heterogeneous substances of natural origin continue to be used in addition to the highly purified products of chemical syntheses. Biotechnology-based products in particular are chemically complex. These usually have counterparts in international standards, but the inherent heterogeneity makes direct interchange unworkable. In these cases, careful characterization of the compositional and biologic profile allows for lot-to-lot consistency.

Existence of a reference standard used in a compendial procedure can in effect transfer the quality standard from

print to the contents of the reference standard vial. Specifically, the content of the drug product is assayed relative to the USP Reference Standard, which is taken to be 100%. The late C.A. Johnson was fond of stating that the printed standard turning yellow was not the same as a yellowing reference standard.

The Committee of Revision takes steps relative to the continuing acceptability of any specific lot of a USP Reference Standard. Publication of a list of current items in each *Pharmacopoeial Forum* keeps the collection up to date in this regard, as well as indicates which are new, have been deleted, or are unavailable.

PARTICIPATION

Food and Drug Administration

Close working relations with the FDA continued as a hallmark of the revision program, both with individual scientists and with FDA laboratories and centers. Formal liaison efforts were conducted primarily through the Compendial Operations Staff in the Center for Drug Evaluation and Research of the FDA. Staff are responsible for obtaining and coordinating agency comments on proposals appearing in the *PF* and for serving as an official point of contact with the Center. They have been effective in contributing many suggestions for improvement as well as a greater degree of consistency between FDA and compendial requirements. Each subcommittee has an ad hoc reviewer assigned by the FDA to ensure communications.

The National Center for Drug Analysis in St. Louis, MO, was a constant, valued, and cooperative participant in the revision process for nearly 3 decades. This laboratory continued from past cycles to do extensive development and review of tests and assays. During this cycle, it continued as the primary FDA participant in the ongoing evaluation of established and proposed new USP Reference Standards. Moreover, careful review was given to many General Chapters and issues in harmonization. The FDA is the single most productive outside source of scientific data and information.

Industrial Cooperation

The *U.S. Pharmacopeia* and scientists in industry interact in a number of important ways (13). The pharmaceutical industry is highly quality conscious; thus the program of a standards-setting body is of pervasive interest. Many interfaces with industrial scientists can be discerned: they

use USP standards; serve as members on the General Committee of Revision; serve as members on the Board of Trustees and on appeals bodies and as delegates to the USP Convention; they propose revision and review revision proposals; they serve on USP Advisory Panels, cooperating organization committees, and panels; they help develop USP Reference Standards; and they purchase USP publications and reference standards. Of these, the most important is that they observe the standards, consistent with the original intent (Fig. 1) of the *U.S. Pharmacopeia*.

Participation by individual

Nearly equal numbers of industrial and academic scientists are involved with USP and NF standards determinations, and 10 of 20 DSD Executive Committee members are industrial. An average of half of the DSD Executive Committee consisted of industrial scientists during the last three cycles. The DSD Executive Committee is the policy-setting body and addresses all broad-interest topics. Pharmaceutical technology is the predominant category of information discussed. Other participants include government scientists and medical and pharmacy practitioners.

Participation by manufacturers

Industrial participation on advisory panels, or the General Committee of Revision itself, in addition to industrial interaction on scientific proposals to and from the USP, represents a substantial time demand for any single company. The enormous amount of laboratory work that supports the pharmaceutical and analytical technology incorporated in USP and NF monographs should be emphasized. In terms of economic value, all other participation does not match the cost of laboratory experiments performed by the industry. Indeed, it is what can be done at the bench and on the manufacturing floor that determines what can or cannot appear in the *U.S. Pharmacopeia*.

It should not be concluded that the USP relies entirely on comments from a single manufacturer. There are other interested parties. Testing may be performed as deemed necessary to supplement or corroborate results reported by or disputed among manufacturers. USP laboratories develop data to enable the Committee of Revision to decide on standards establishment and revision. Note that commercial products are not tested by the USP to determine compliance with official standards. Rather, USP testing is called on as necessary to 1) test methods that are considered for new or revised standards in monographs, 2) test products to generate data for the USP Committee of Revision when information needed for

standards development and improvement is not forthcoming from other sources, 3) participate in collaborative studies, 4) test materials considered for use as USP Reference Standards, and 5) test USP Reference Standards periodically for degradation.

Industrial Organizations

Revision of the *U.S. Pharmacopeia*, particularly in development of new General Chapters and tests and assays for specialized products, continues to progress through the strong and proactive participation by industry.

No recent pharmacopoeia was issued without notable contributions by the Pharmaceutical Research Manufacturers of America through its standing technical committees in quality control, statistics, and biologicals. Careful reference to the *PF* also will reveal many contributions by scientists from individual member companies.

The Council for Responsible Nutrition (CRN) and the Consumer Health Products Association (CHPA) contribute to new standards for over-the-counter articles. Growth continued on the multiple vitamin-mineral combinations described by class monographs for cough and cold remedies, which include a very large number of products.

Parenteral Drug Association (PDA) members and committees focus on standards for sterile products, testing, and environments.

Self-Regulation

A continuing element of the USP seldom remarked on (13) is the fact that our program of public standards represents the substantial realization of self-regulation by the pharmaceutical industry. Self-regulation is an ideal. It is a natural ideal for free peoples and a historic impulse in our national life. However, it is not directly achievable as a uniform or practical principle. Pressures of money and competition and differing relative values get in the way. What is an obvious improvement to one is an inconvenience or an unreasonable expense to another. Unpopular causes are not written into most corporate job descriptions, especially when the employer suffers the costs of that employee's self-regulatory campaign and, more starkly, sees competition that gets a free ride. In this regard, one should recall the extensive industrial cooperation described above. This fact is remarkable, and it is so important that all understand this characteristic of the *U.S. Pharmacopeia* repeated here.

What is necessary to achieve the ideal of self-regulation is an instrument to transform individual efforts.

Table 2 1990 to 2000 Committees of Revision

870	New monographs adopted
23	New general chapters adopted
270	Deleted monographs
9240	Individual revision actions proposed in <i>Pharmacopoeial Forum</i>

That instrument is a neutral but authoritative institution. It can insulate individuals and diffuse responsibility while maintaining necessary accountability. The truly knowledgeable can act on their natural inclinations to self-regulate but remain insulated from all negative counterforces. That is one primary reason the USP is so productive, even though it is a small organization.

The ideal of self-regulation realized through institutional transformation has another consequence. It explains why USP standards are not limited in practice to the “lowest common denominator” but are the “acceptable common denominator.” Although our subcommittees strive for consensus when a number of parties are involved, or acquiescence of one party, USP standards are held to the more idealistic level of knowledgeable self-regulation. Consensus is not prerequisite.

Often quoted is de Tocqueville’s observation that Americans like to form associations to accomplish mutual purposes without the burden of additional government. This is fueled by our spirit of voluntarism. The USP effort, starting in 1820, certainly fits that description (14). However, why can’t trade associations be the vehicles of effective self-regulation? All who have worked with these know it cannot be done readily when any member’s vested interest is seriously threatened. Consensus in the strictest sense applies. The same type of experts, if elected to the USP Committee of Revision, can take that last essential step in self-regulation: they can set meaningful end-product standards free of strict consensus. It is the majority vote that decides. It is the unique nature of the USPC that effects that transformation. It does what deserves to be done, but without all the baggage that comes with more government.

To appreciate the impact of this element, consider the sheer magnitude of the USP revision effort. Table 2 gives summary facts about the magnitude of recent USP activity. Each of these pharmacopoeial revisions involved industrial participation. Ask yourself: How could so many things get done unless participants of all types were willing or at least favorably disposed? They are so disposed because in this quality-conscious industry, people want standards and because most would be willing to regulate themselves.

INTERNATIONAL RELATIONSHIPS

International Harmonization

The phenomenon of globalization of pharmaceutical manufacturing and distribution, already evident in the excipient monographs of the NF 18, continued throughout the revision cycle leading to the USP 24-NF 19.

Although originally founded as an organization to standardize medicines in the United States, the USP and its products and services are now known and used throughout the world. In today’s transnational and multinational economy for pharmaceuticals, the USP needs a strong international presence and influence for its survival as well as for continued growth and recognized leadership. Economic forces are driving major trading parties to affiliate to reduce trade barriers. Integral to this process is harmonization of requirements, regulations, and standards governing the approval and marketing of drugs, devices, etc., by governments. (See also *Harmonization of Pharmacopoeial Standards* in the second edition of this Encyclopedia.) In view of the contemporaneous publication of that chapter, also prepared here, only formal publication agreements are discussed herein.

Two organizations account for harmonization of new and revised standards: the Pharmacopoeial Discussion Group (PDG) and the International Conference on Harmonisation (ICH). Primary impact is attributed in this cycle again to the PDG consisting of the USP with the Japanese and European pharmacopoeias. Joint open conferences held on an international basis were crucial to any progress here because these ensured direct contact among experts from the three pharmacopoeias (see “Open Conferences and Meetings,” earlier).

Harmonization is not a one-time event, and it does not imply superimposability of texts. Residual disharmony can exist at the end of any specific attempt to harmonize standards. Iterations of harmonization, already evident, will be the norm in the future. Refer to the *PF* as the essential source of any future understanding or tracking of harmonization topics or sequences.

One serious discrepancy exists between requirements in this Pharmacopoeia and ICH guidelines beyond the relative mandatory status. USP-NF requirements are enforceable by U.S. federal and state laws and regulations. The standards give the attributes of acceptable articles already used in healthcare. A key contrast can be seen in the strict focus of the ICH, which is explicit in treating new drugs, that is, those not yet in use. The situations differ dramatically in practical consequences and breadth of application. Therefore, the goal of harmonization in some cases is not currently

achievable because justification does not exist to disturb many established products in favor of the most recent new drug approval practices.

Foreign Use of the USP and NF

Evidence of the utility of the USP beyond North America is found in the many orders received for USPC publications (USP, Supplements, *Pharmacopoeial Forum*) and reference standards. In return, the contributions of foreign scientists in questioning existing standards and in commenting on *Pharmacopoeial Forum* proposals frequently reveal insights not otherwise focused in domestic queries and comments. Although many of these insights that originate in foreign countries are passed to the USP through domestic affiliates, committee members usually are aware of the originator's contribution. Foreign scientific input is extensive and receives the same consideration on merit as does domestic comment.

Limitations on foreign use of USP standards arise from that same high technological level of the standards. Instruments cost, availability, and maintenance prospects set high barriers where foreign exchange is a problem for a country. Arranging for training of pharmaceutical scientists, and then keeping them, is also a limiting factor.

The Drug Information Division selects the person from a large pool of candidates for nomination in the particular class of service. For example, the nominating committees for the 1990–1995 Committee of Revision screened a pool of over 1200 candidates before they agreed on 228 nominees for 114 positions, representing 45 classes of service.

The advisory panels have an even more active program to identify highly qualified persons from other countries. As the USP DI database becomes more widely known and used outside the United States, the USP seeks qualified persons from countries using USP drug information to provide advice on the utility of the information in those countries and advice on how the drugs in the database are used in those countries. In this way, the database can be enriched and made more useful to a greater number of countries.

OTHER PHARMACOPEIAS

International Pharmacopoeia

The USP has established formal arrangements with individual countries or pharmacopoeias that are not direct participants in harmonization, although the practical

effects may be the same. As noted above, harmonization per se is the subject of a separate chapter in the second edition of this Encyclopedia.

Canada

Canada has a special relationship with the USP. The USP-NF has been officially recognized by statute as a legal compendium in Canada since 1954. Approximately 95% of drugs claiming compliance with compendial standards in Canada follow the USP-NF. The USP is proud of its status in Canada and values the contributions of its Canadian members. Representatives of the Therapeutic Products Programme (TPP) of Health Canada and the Canadian Pharmaceutical Association are members-at-large of the U.S. Pharmacopoeial Convention. Relations between the Health Protection Branch and the USP are cordial; the USP seeks to work closely with the TPP, as it does with the FDA. Six Canadians were elected to the USP Committee of Revision for the 1995–2000 period, and 45 Canadians have been appointed to USP advisory panels. Canadian pharmaceutical scientists, physicians, pharmacists, and other healthcare professionals take an active interest in the USP. In addition to the USP-NF being official in Canada, the USP drug information database *USP DI* covers all drugs on the Canadian market as well as on the U.S. market.

Argentina, Mexico, and Brazil

The USP initiated discussions with compilers of the three other active pharmacopoeias in the Western Hemisphere. USP scientists, practitioners, and staff have been intimately involved in meetings and programs, both in standards and in information. These successful efforts put down the groundwork for the first agreement with Argentina and subsequently with Brazil and Mexico between the USP and other Western Hemisphere pharmacopoeias that allows use of any part of the USP or NF, in English or Spanish, as an aid to elaboration of a national pharmacopoeia. Establishment of the same standards obviates the less desirable effort of harmonization. Adoption of the NAFTA pact within Canada, Mexico, and the United States stimulated progress on this bilateral basis.

The *Farmacopea de los Estados Unidos Mexicanos* (FEUM) is the Mexican Pharmacopoeia. Stimulated by the signing of the North American Free Trade Agreement (NAFTA), the USP and the FEUM initiated a dialogue in January 1993 to explore opportunities for harmonization. Originally conceived as a semiannual meeting after

the Pharmacopoeial Discussion Group (PDG) model, the USP has hosted five visiting scientists from Latin America.

China

The *Pharmacopoeia of China* contains volumes dealing with both Western and traditional Chinese medicines. A series of informal visits has taken place at the initiation of the Chinese Pharmacopoeia Commission (ChPC). The USP has been host to visiting scientists from China and has had seven scientists from the Chinese Pharmacopoeia in residence for periods up to 4 months each.

International Pharmacopoeia

The World Health Organization (WHO) took over the programs begun by the League of Nations, based on the work of the Brussels conferences in the early 1900s. Special emphasis was directed at the establishment of the *International Pharmacopoeia* (IP). The IP differs from national and regional pharmacopoeias in that it is not directly mandatory in few countries. Focus is on the needs of developing countries where acquisition and use of modern, automated analytical technologies may be difficult. The IP provides analytical methodologies that can be used where more advanced technologies are not readily available. The WHO program for International Non-proprietary Names is coordinated with the U.S. Adopted Names Council. Over the years, members of the Committee of Revision and members of the USP staff have served on the Expert Committees on Specifications for Pharmaceutical Preparations and Antibiotics, continuing the USP's long-standing commitment to WHO drug quality programs.

In accordance with Article 41 of its Constitution, the WHO published a first edition of the *International Pharmacopoeia* in 1952. Because no official national representatives were part of the Commission, the *International Pharmacopoeia* was considered not to have legal force. That legal characteristic has continued. Nevertheless, the *International Pharmacopoeia* continues to attract the energies of pharmaceutical scientists from many countries. The *International Pharmacopoeia* has been positioned to address national needs not satisfied by the large regional pharmacopoeias such as the USP. The USP must be in accord with well-equipped analytical laboratories, technologically advanced manufacturers, highly varied and competitive markets, and therapeutic strategies and expectations characteristic of our intensive, personalized medical care. In contrast, the *International Pharmacopoeia* seeks to publish standards

using technology appropriate to some small- and medium-sized quality control laboratories (20). Basic tests to check drug identity and to exclude substantial decomposition are notable and extensive achievements by WHO experts. A scheme for certification of suppliers is also published.

Color tests have fallen into disuse in North America as convenient but analytically powerful instruments have come in the budgetary range for control laboratories. This condition does not yet pertain to much of the world. Attention to the provisions of the *International Pharmacopoeia* in those countries can make important contributions to the drug product quality received by their populations. To help realize this, the WHO has supplied detailed guidance for staffing and equipping small, medium, and large analytical laboratories with increasing degrees of technology and instrumentation (20).

The present scope of the *International Pharmacopoeia* continues to be that defined by Wieniawski (21), that of furnishing quality specifications for drug substances and general requirements for dosage forms. Thus, no monographs for individual dosage forms are published in the *International Pharmacopoeia*. WHO leadership may intend to include dosage forms in the future, but a more definitive statement cannot be made at this writing. The three volumes of the third edition give standards for "essential" drug substances (22).

European Pharmacopoeia

European Pharmacopoeia provisions now take precedence over all European national pharmacopoeias.

British Pharmacopoeia

Many similarities existed between the *British Pharmacopoeia* and the USP. Common elements of origin, continuing commerce, and a long history of cooperation have resulted in close correspondence in critical details. Both are legal instruments, both are recognized in the laws of countries other than those of origin, both establish standards for dosage forms as well as for bulk pharmaceutical chemicals. Both use experts from industry, academia, and government at all stages of standards development. Also, for most of its history, the *British Pharmacopoeia* was not a direct government effort.

Other National Pharmacopoeias

There are national pharmacopoeias established by governments to meet perceived needs for compendial standards for locally produced articles. A number of these

have published recent editions as evidence of continuing commitment, but it is often difficult to locate a U.S. bookseller for these. Cities of publication are Berlin, Paris, Prague, Rome, Tokyo, Peking, Seoul, Stuttgart, and Taipei. Most countries require imported articles to conform to one or another widely recognized pharmacopoeia, such as the USP or the *British Pharmacopoeia*.

USP Products and Services in Other Countries

Since 1982, the USP has developed distributorships in other countries to meet the needs of customers more directly. The Zentrallaboratorium Deutscher Apotheker [Central Laboratory of the German Pharmacists Association (ZL)] in Eschborn, Germany, was the first distributor and now serves clients in Europe and in the Middle East. The largest distributor is Promochem GmbH, with headquarters in Wesel, Germany, and branches throughout Europe. The British Pharmaceutical Society distributes Reference Standards throughout the United Kingdom. The Society for the Japanese Pharmacopoeia became a distributor in 1991. In Canada, at least two firms distribute Reference Standards. Distributor information appears in each bimonthly Reference Standard Catalog published in *Pharmacopoeial Forum*.

Agency for International Development

The USP had a cooperative agreement with the U.S. Agency for International Development (USAID) since 1992 to assist developing countries in establishing programs of pharmaceutical management (including procurement, storage, and distribution) and control (including country-specific formularies and drug information resources). This program is jointly funded by the USAID and the USP.

U.S. Department of Commerce

In 1992, the Department of Commerce (DOC) established the Special American Business Internship and Training (SABIT) program to train scientists from the newly independent states (NIS). The USP secured an agreement whereby the DOC sponsors travel expenses for six Russian scientists under the USP Visiting Scientists Program to learn techniques in drug analysis at the USP Drug Research and Testing Laboratory. To date, two scientists have each completed 4-month training programs. The laboratory in which these scientists will work will be

established in Moscow and funded by the World Bank. The International Foundation for Drug Efficacy and Safety (IFDES), a not-for-profit group chartered under Russian, Swiss, German, and U.S. laws, is a voluntary group working with the NIS to assist in restoring their programs of drug supply regulation and quality control.

PHOTODECOMPOSITION OF DRUGS

Hanne Hjorth Tønnesen

University of Oslo, Oslo, Norway

INTRODUCTION

Numerous compounds degrade when exposed to light. Some light-sensitive drugs are rapidly affected, either by natural light (particularly ultraviolet) or by artificial light (e.g., fluorescent light). This may lead to a change in the physicochemical properties of the product, e.g., a precipitate is formed, the product becomes discolored or cloudy, a loss in viscosity is observed, or the active ingredient undergoes photodegradation, which may not be visually detectable. The most obvious result of drug photodecomposition is a loss of potency of the product. Consequently, this can result in a drug preparation that is therapeutically inactive. Although this does not occur often, the study of photodegradation is important because the decomposition products that might occur in the formulation during storage may be toxic. Such products may also develop by the action of sunlight on the epidermal layers of the skin or in the eye of patients receiving the drug and may thereby cause photosensitivity reactions. Photostability testing is therefore an essential part of product development and is needed to ensure that satisfactory product quality is maintained during practical usage.

In this chapter, various aspects of drug photoreactivity are presented. Common photochemical reactions by which drugs have been found to decompose are described. The influence of formulation factors, e.g., excipients, on product stability is discussed. Finally, variables that have to be considered in photostability studies are noted.

PHOTOREACTIVITY OF DRUG SUBSTANCES

The photochemical reaction is a complex process. During the last decade, a body of data relating to drug degradation pathways has been accumulated and recently reported (1–3). The light-sensitive drug molecules may be affected directly or indirectly by irradiation, depending on how the radiant energy is transferred to the drug molecules. Primary photochemical reactions occur when the drug molecule itself absorbs energy, i.e., when there is a certain overlap between the absorption spectrum of the molecule and

the incident radiation. Many drug substances are white, and thus the degradation depends primarily on the amount of UV radiation absorbed by the material. Colored substances absorb light in the visible region of the spectrum. Degradation products formed during shelf life can be colored and thereby change the overall absorption characteristics of the formulation. Any overlap of the product absorption spectrum with the photon source impinging on it has the potential to cause a photochemical change. One consequence may be that a drug substance with an absorption spectrum that does not overlap with the photon source still photodecomposes in a formulated product. This takes place in a process called photosensitization. The energy absorbed by the nondrug molecule is imparted to the active ingredient, which subsequently degrades. The absorbing component is called a photosensitizer. The sensitizer may transfer the absorbed energy completely and not be altered itself in the process, but in many cases it will undergo some degradation. Photochemical stability of a drug compound in a formulation therefore cannot be predicted from only the absorption spectrum/stability studies of the drug in a pure solvent. Stability studies of the drug substance in the final product must also be considered.

Light acts as a reactant and never as a catalyst in a photochemical reaction. Light energy (a photon) is absorbed by the promotion of an electron from an initially occupied, low-energy orbital to a high-energy, previously unoccupied orbital. The result is an electronically excited molecule. In the singlet state, the electron spins are paired (antiparallel), whereas in the triplet state, the electron spins are unpaired (parallel). Excited states are both better donors and better acceptors of electrons than are ground states. They are unstable and often return to the ground state by dissipating their energy as heat and/or light. In many cases, the excited state leads to the formation of high-energy products such as free radicals or radical ions. Photochemical processes usually occur in two stages. The primary reaction is the reaction directly attributable to the absorption of a photon, i.e., it involves the excited state. This reaction does not depend on temperature for activation of the molecules. The primary photochemical reaction, however, will often be followed by secondary (thermal)

reactions occurring from the intermediates produced by the primary photochemical process (e.g., radicals, radical ions). These intermediates can eventually react through "dark" reactions to form the final, stable products. In some cases, the final products may resemble the products of the purely thermal reaction (dark reaction from the molecular ground state), but this similarity is coincidental.

Drugs are usually stored in contact with atmospheric oxygen and are always in contact with dissolved oxygen in circulating blood and living tissues. Energy transfer from an excited drug molecule will often lead to the formation of reactive oxygen species (ROS)(4). A type I photosensitized reaction proceeds through the transfer of electrons or protons. The resulting cation or neutral radical is likely to undergo further reactions. In the absence of oxygen, dimerization or recombination can result. When oxygen is available in sufficient concentrations, molecular oxygen will rapidly add to the radical, leading to the formation of peroxy radicals. These radicals are highly reactive and tend to abstract a proton from neighboring molecules. This sequence is often described as a chain reaction. In another photosensitization mechanism, an electron is transferred from an excited drug molecule to ground-state oxygen to give an anion radical known as superoxide. Superoxide is a powerful oxidizing agent and very toxic to biological systems.

Most molecules are singlet in the ground state. The oxygen molecule is unusual in that it is a triplet. In a type II photosensitized reaction, energy transfer from an excited drug molecule to ground state oxygen gives excited oxygen in the singlet state. Singlet oxygen is very reactive toward organic molecules and can lead to the formation of hydroperoxides by addition to olefinic bonds.

A relationship between structure and photoreactivity can be difficult to predict, but certain structural types are

known to have a high possibility of photodecomposition. Examples are shown in Table 1. Olefinic carbon-carbon double bonds can undergo *cis-trans* isomerization and may cyclize as a result; arylacetic acids are likely to decarboxylate; and some amines *N*-Dealkylate and haloaromatic compounds tend to dehalogenate. A drug can also sensitize its own degradation or drugs in a mixture can undergo cross-sensitization (5). Unfortunately, several pathways are reported for many drugs, complicating the elucidation of mechanisms. An extensive list of common photoreactions of drug substances was compiled by Greenhill and McLelland (1).

A drug that displays photochemical reactivity in vivo may cause adverse photosensitivity effects in patients. Sunlight penetrates the skin to a sufficient depth to reach molecules circulating in the surface capillaries, or it can react with compounds accumulated in the eye. In both cases, sunlight may convert the drug to a toxic decomposition product or induce the formation of ROS. Singlet oxygen and superoxide are both toxic to human tissues. Cutaneous photosensitization can be classified as phototoxicity, in which the skin reactions derive directly from photosensitized damage to the cellular components of the skin, and photoallergy, in which the mechanisms of the immune system are activated. Phototoxic reactions may be oxygen-dependent (photodynamic) or oxygen-independent (nonphotodynamic). In some cases, photodegradation products can circulate in the blood stream and cause damage to deep-seated organs. However, it should be noted that a combination of drugs and light can be beneficial, such as in the treatment of vitiligo, psoriasis, and skin cancer and in the development of site-specific drug-delivery systems.

The rate of a photochemical reaction is in general dependent on the rate at which light is absorbed by the system (i.e., the number of photons absorbed per second) and the efficiency of the photochemical process (i.e., the quantum yield for the reaction). The quantum yield is usually independent of wavelength. A primary photochemical reaction follows first-order kinetics in a formulation that contains the drug substance in a low concentration (6). The kinetics is more complicated at higher concentrations. Most of the light will then be absorbed close to the sample surface. The drug molecules inside the volume become protected from irradiation and do not participate in the primary reaction (inner filter effect). If the concentration of the active compound is high (absorbance approaches 2), the degradation kinetics may follow a pseudo-zero-order rate. In this case, essentially all the light is absorbed by the drug, and the rate-limiting factor is the light intensity. It is, however, the overlap integral that determines the rate of the reaction. Because of a small overlap integral, first-order kinetics can be

observed even if the product contains a large amount of the absorbing species. The rate of disappearance of the drug in a sensitized reaction may be dependent on both the drug and the sensitizer concentrations, i.e., the degradation process follows second-order kinetics. It is difficult to use reaction order to characterize photodegradation in the solid state. The photochemical processes take place on the product surface, and the change in total concentration measured as a function of irradiation time does not necessarily follow any particular reaction order model (7).

INFLUENCE OF PRODUCT FORMULATION ON DRUG PHOTOSTABILITY

Most photochemical reactions are affected by the medium, i.e., both by excipients and by the type of formulation (8). Examples of formulation factors influencing product photostability are given in Table 2. A drug substance in an intravenous infusion product is likely to be presented as a dilute solution, whereas the active compound of a topical preparation represents a situation part way between the solution phase and the solid state. Parenteral solutions ensure high light impingement on the drug molecules owing to a large surface-to-volume ratio and usually a low drug concentration. In the solid state; the depth of light penetration is determined by the characteristics of the sample surface. For example, a capsule and a tablet have different light-scattering characteristics and different surface area-to-volume ratios.

Cosolvents, such as ethanol or higher alcohols, and surfactants are often used in a formulation to enhance the solubility of sparingly soluble compounds or to modify the stability of the drug molecule. Cosolvents will change the polarity and, in some cases, the viscosity of the medium. This may influence the photochemical reactivity of a compound. An increase in solubility will change the sample absorbance. Dissolution of particle aggregates leads to an increase in light impingement on the separate drug molecules. Surfactants will form micelles that can interact with drug molecules. This can lead to a change in drug molar absorptivity or in reactivity owing to a micro-environmental effect. Cosolvents and surfactants can have a photostabilizing or photodestabilizing effect on the product, as demonstrated for phenobarbital and nitrofurazone, respectively (9, 10).

For many drug substances, the photodegradation process is highly dependent on the ionization form of the molecule (e.g., ciprofloxacin, midazolam, and chloroquine) (11–13). The dicationic form of the antimalarial drug mefloquine is almost not photolyzed, whereas the monocationic and neutral forms of the molecule readily undergo photodecomposition (14). The oxygen concentration plays an important role in the process. Flushing the mefloquine samples with helium during irradiation leads to a substantial increase in the degradation rate. Destabilization by removal of oxygen is also demonstrated for other drugs such as nitrazepam (15). For oxygen-sensitive compounds, a stabilizing effect would ordinarily be obtained by purging the solution and headspace with an inert gas. However, it should be recalled that for reactions

Table 2 Formulation factors that may influence the photostability of drugs

in which oxygen participates only catalytically, even trace amounts of residual oxygen may render the product unstable. An increase in ionic strength is reported to have a photostabilizing effect on certain drugs by providing a protective film of solvated ions around the reacting molecule (16). This effect is not observed in mefloquine (14). On the other hand, an increase in degradation rate was measured as a function of phosphate ion concentration in the buffer system used. The phosphate ion is known to influence the photochemical properties of compounds (e.g., tyrosine) by facilitating proton transfer from the excited state of the reacting species (17). Various types of buffer salts exert different effects on the photodegradation process, as demonstrated for the drug daunorubicin (18). Buffer salts such as citrate can also change the absorption characteristics of the formulation by forming complexes with other components present, leading to products that absorb in the visible part of the spectrum.

In many cases, the degradation rate is highly dependent on the presence of trace metals. A variety of chelating agents and antioxidants is available for use in pharmaceutical preparations. The most commonly used in aqueous systems are bisulfite and EDTA. Many drugs have shown reactivity toward bisulfite. A significant photodestabilizing effect on epinephrine has been demonstrated (19). Fe(III)-EDTA chelates are reduced by superoxide quite rapidly. EDTA therefore will not inhibit degradation of drugs in systems in which the iron-catalyzed Haber-Weiss reaction plays an important role. The effect of antioxidants and chelating agents on drug instability must be carefully evaluated before use. Other excipients such as tonicity adjusters, colors (see below), and sweetening agents could further interact with commonly used stabilizers or influence the photoreactivity of the drug substance (20–23).

Photoprotection by spectral overlay with suitable excipients can stabilize various drugs and preparations. Incorporation of the yellow compound curcumin in the shell of soft gelatin capsules was demonstrated to have a protective effect on drugs such as nifedipine, chloramfenicol, frusemide, and clonazepam (24). The addition of colors is further shown to stabilize drugs in tablets, solution, and topical preparations (25). A mixture of colors or pigments, however, can undergo catalytic fading (26) or induce degradation of other components in the formulations by radical formation (27, 28).

Photodegradation in the solid state takes place only at the sample surface. The degradation rate is therefore dependent on factors that will influence the depth of light penetration, i.e., change the absorption and reflection at the surface (e.g., particle size, crystal modification, color, thickness of powder bed, and coating of the individual

particles or the dosage form). Mefloquine, chloroquine, carbamazepine, and furosemide are examples of drug substances that show different decomposition rates dependent on their polymorphous modification (29–32).

A change in drug photoreactivity by complexation with suitable carriers can be observed both in solution and in the solid state. Metronidazole was found to be less sensitive to irradiation after complex formation with sodium urate (33). The extent of photodegradation of various drugs including phenothiazine has been reduced by inclusion complexation with cyclodextrins (34–36). There are marked differences in stabilizing effect among various types of cyclodextrin. Liposomes or a combination of liposomes and cyclodextrins are also demonstrated to improve drug photostability (37, 38).

The method used most commonly to protect photosensitive drugs is to place the preparation in a protective market pack or in a colored or amber immediate container. During storage and use, the protective market pack may be removed. In cases in which the immediate container is made of transparent glass or plastic material, little protection against radiation is obtained. Amber containers offer better protection but vary in thickness, chemical nature (plastic), and degree of coloration, which may influence their photoprotective properties. The stabilizing effect of amber glass as the only means of photoprotection is not satisfactory for highly photolabile drugs such as molsidomine (39). Even brown glass can offer inadequate protection, as demonstrated for drugs like epinephrine, isoprenaline, and levarterenol (40). The destabilizing effect of the container was attributed to release of alkali and traces of heavy metal ions that impart color to the glass.

PHOTOSTABILITY STUDIES

It is essential to obtain information about the photoreactivity of a drug molecule as early as possible in the formulation process (41). Knowledge about the photochemical and photophysical properties of a drug substance is important for the handling, packaging, and labeling of the product. One approach to evaluate overall photosensitivity is to design a photoassay, as noted in an earlier report (42). A basic protocol for testing new drug substances and products for first submissions is described in the ICH Guideline for photostability testing, which has been implemented since January 1998 (43). The Guideline notes that photostability testing should be an integral part of stress testing. Although the proposed test is reasonably simple to conduct, there are some variables that have to be controlled carefully during photostability studies.

Problems related to the application of the current guideline are discussed in a recent review (44). Important factors to consider are irradiation source, irradiation level, calibration, and presentation of the samples (45–48).

Various irradiation sources can be used in the stability studies of drugs and drug products. The source(s) selected should be comparable in spectral distribution with those to which products are exposed in practical use. The portion of radiant energy from the sun reaching the Earth includes the UVB (290–320 nm), UVA (320–400 nm), and visible (VIS) light (400–700 nm) ranges. It may be difficult, however, to predict the exact amount of UV and VIS irradiation to which the product is exposed during shelf life. The irradiation conditions therefore should provide a “worst-case” exposure. The ICH Guideline gives two options for the selection of irradiation source. Option 1 addresses exposure to outdoor daylight or window glass-filtered daylight. In most cases, a source providing glass-filtered daylight (ID65 according to ISO 10977) would be appropriate. Option 1 can be achieved by use of a fluorescent lamp that combines UV and VIS outputs or by use of a xenon or metal halide lamp. To simulate indoor conditions, it is necessary to use a window glass filter in combination with sources producing significant radiation below 320 nm (e.g., xenon and metal halide lamps, near-UV fluorescent tubes). Option 2 in the ICH Guideline addresses exposure to indoor fluorescent light (cool white). During shelf life the product is likely to be exposed to a mixture of natural light through window glass and artificial light (e.g., light from a fluorescent tube). A UV source is therefore added in Option 2 to cover the spectral region of natural light that may reach the sample. According to this option, the test is more severe than that for indoor fluorescent light alone, but it does not adequately simulate daylight through window glass.

The ICH Guideline recommends a total exposure of 200 Wh/m^{-2} in the UV range of 320 to 400 nm and 1.2 million lux hours in the VIS range (400–700 nm). For an average source simulating window glass-filtered daylight, a total irradiance of 200 Wh/m^{-2} in the UV region corresponds to approximately 0.45 million lux hours in the visible region. A test run with the end criterion of 1.2 million lux hours is therefore likely to exceed the requirement of 200 Wh/m^{-2} with a factor of up to 2.5 to 3 when a lamp according to Option 1 is selected, unless precautions are taken (44). In this context, Option 2 may be easier to handle because the UV lamp can be turned off when the desired UV exposure is obtained.

The ICH Guideline offers no guidance for the choice of Option 1 or 2. Although the options are not scientifically equivalent, they could be regarded as equivalent for purposes of a confirmatory study. It is important, however,

to combine the results with knowledge already obtained from other tests before labeling decisions are made.

The overall illumination is specified in the ICH Guideline, whereas the irradiance level is not indicated. An irradiance level that is high enough to accelerate the test without causing unwanted temperature effects must be selected. Tests conducted at significantly different irradiance levels could not be compared unless correlation has been established. The distance between the source and the sample surface should be defined to keep the radiant intensity constant. The irradiance at the specimen surface may also change as a function of the sample location inside the test chamber. The UV and visible levels should therefore be measured across the test chamber to ensure that the samples are placed at points of equal irradiance.

Even though the lamps are changed at defined intervals as specified by the producer, it is essential to calibrate the light source and periodically monitor its irradiance to obtain the predetermined exposure value. For instrumentation without a built-in sensor, calibration can be performed manually. The ICH Guideline recommends the use of a calibrated radiometer or a validated actinometric system to monitor the exposure in the UV region and a calibrated luxmeter to determine the overall illumination in the visible range. Neither will provide any information about the spectral distribution of the irradiation source. A UV filter radiometer is a broad-band meter designed to measure incident radiation in the UV region. An optical filter limits the spectral responsivity to a certain band (e.g., UVB and UVA). Unfortunately, there are no international standards for the filters and radiometers from different manufacturers, and therefore they may measure different fractions of radiant energy. A luxmeter will measure light as perceived by the human eye, i.e., it has a photopic response curve. The photopic sensitivity range of the human eye is approximately 380 to 780 nm, with the highest sensitivity at 555 nm. Neither the radiometer nor the luxmeter have a constant spectral responsivity over the actual wavelength range (i.e., the relative weighting given to the different wavelengths is not constant). The devices should be calibrated by the manufacturer at regular intervals. If the meters are used as received, they are well suited for measuring evenness of irradiance across the sample area and changes in total output with time. However, they cannot be used to give an absolute measurement of irradiance or to compare irradiance between sources unless they are calibrated specifically for each source (44). The ICH Guideline proposes quinine actinometry as an alternative to the radiometer for calibration in the UV range. The total irradiance is then determined by using a reaction of known photochemical efficiency (47, 49).

Samples may be placed in clear or amber glass, in plastic, in marketed containers, or in a Petri dish during exposure. The spectral transmittance characteristics of the container will influence the results. For example, the illuminance inside clear glass is higher than that inside amber, blue, or green glass, and the spectral distribution is different. Other factors to consider are the orientation of the sample container (upright, inverted, or sideways), thickness of the container material, and surface area/volume (weight) ratio. It is recommended in the ICH Guideline that the sample thickness should not exceed 3 mm for drug substances in the solid form. Preparations such as tablets or capsules should be spread in a single layer. The primary disadvantage in using a protective container is that a significant increase in temperature can be expected. Therefore, dark controls should be placed alongside the authentic sample. Stirring or shaking of samples during exposure is not recommended for the purpose of photostability testing, according to the ICH Guideline.

PHYSIOLOGICAL FACTORS AFFECTING ORAL DRUG DELIVERY

Clive G. Wilson
Bridget O'Mahony
Blythe Lindsay

University of Strathclyde, Glasgow, United Kingdom

INTRODUCTION

Thirty years on from the explosion of commercially successful applications of targeted and controlled release pharmaceutical formulations, it is evident that there remains a need for further refinements and innovations in the field of drug delivery. Many of the larger corporations focus on the use of novel technology for extension of a product life cycle; however, in many cases solubility and permeability issues limit the application of such technologies. Additional complications arise due to inter- and intrasubject variability, compliance, and chronobiological variation in disease incidence.

Variability has many causes and an understanding of the factors that predict that certain therapeutic approaches will work better for some individuals than in others is key. This article will consider a few such examples from the literature and our own studies, which we hope will illustrate how physiological factors impact on disease treatment.

ORAL DRUG DELIVERY

In most cases, oral drug delivery is the cheapest and most convenient method of dosing. Unfortunately, it is difficult to achieve a precise control of the plasma-concentration-time profile by this route due to marked intra- and intersubject variation in gastrointestinal transit even under the rigidly controlled conditions of the clinical trial. Daily patterns of food intake, activity, and posture are large contributors to this variation. Drugs that are only absorbed from specific areas of the gastrointestinal tract, i.e., have a narrow "window of absorption," will be most affected by alterations in transit. The major determinants of this variation will be the amount of food and drink consumed.

In the western world, the average adult consumes and excretes between 1.5 and 2.5 L of fluid per day. The liquid is consumed as beverages whose intake is closely linked to the level of salt in the diet or as water in the fluid component of food. In addition, metabolic processes

generate approximately 350 ml of water per day. Water turnover in the epithelial tissues of the gut (secretion and absorption) is estimated at 9 L per day and in view of this prodigious flux, we might expect that most of the internal cavities of the body have water in excess.

This is however, not true and certain environments of the gut might be regarded as moist rather than wet: for example, the oropharynx, the esophagus, and most of the large bowel. This lack of water increases the variability of drug delivery to these areas.

ESOPHAGEAL TRANSIT

For dosage forms to reach the stomach they must first pass through the oesophagus, a 25–30 cm long moist hollow tube. It is commonly assumed that swallowed dosage forms pass without hindrance into the stomach unless an underlying oesophageal condition is present. Up to 60% of healthy subjects over the age of 60 years report a problem in swallowing intact tablets (1). To assist swallowing of a tablet, patients are instructed to take a dosage form with plenty of water. It might be expected that simple encouragement and education could encourage compliance. In practice, when patients are presented with a 240-ml glass of water and instructed to swallow a tablet "according to normal practice," they imbibe only two to three mouthfuls (between 50 and 100 ml). Fig. 1 shows the variation in water volume imbibed with a placebo tablet under these conditions. These data suggest that patients are unlikely to be concordant with physician's or pharmacist's instructions.

Water intake and posture are recognized as important factors in avoiding "pill-erosion" of the oesophagus. This condition is usually caused by drugs that are irritant, highly acidic or basic, e.g., NSAIDs, potassium chloride, ferrous salts, tetracycline, and rifampicin (2–4). If tablets are taken without water or when semirecumbent, there is a risk that they may remain lodged in the lower third of the oesophagus. This may result in mucosal damage as the formulation starts to dissolve, causing a high local

Fig. 1 Volume of water swallowed with a capsule when allowed water ad lib. (Data courtesy of Dr. Richard Dansereau, to be published.)

concentration of drug and dehydrating the surface epithelium. In addition, components of the formulation may help to form a strong bioadhesive bond between the unit and the tissue surface, aiding retention.

Esophageal retention frequently occurs even in clinical trials where correct dosing is carefully monitored. Figure 2 illustrates esophageal retention of a radiolabelled fast-dissolving analgesic hard gel formulation administered to a young volunteer. Subjects received two doses of the radiolabelled formulation. In this subject, the first dose cleared normally while the second adhered to the lower third of the oesophagus leading to significant reduction in peak plasma paracetamol concentration compared with other volunteers (Fig. 3).

As we get older, the ability to swallow certain kinds of formulations becomes problematic. In a series of studies conducted at the Queen's Medical Center, Nottingham, it was found that elderly patients had problems swallowing

Fig. 2 Radiolabelled hard gelatin capsule lodged in the esophagus.

hard gelatin capsules. This appears to be due to an inability to coordinate the cricopharyngeal reflex to both water and capsule bolus (5, 6).

GASTRIC EMPTYING

The process of gastric emptying is extremely complex and is influenced by many factors such as presence of food, food content, pH, and posture. Most drugs are not absorbed from the stomach and are therefore dependent on the gastric emptying process to deliver them to their site of absorption. Consequently, the process and factors that affect it have been extensively studied with many conflicting views reported.

The stomach can exist in two states: fed and fasted. The empty stomach has a volume of approximately 50 ml, that increases to about 1 L when full. The fate of a dosage form is dependant on the state of the stomach at time of administration.

In the fed state, the environment within the stomach is infinitely variable in terms of food content. The nature of food intake is not only specific to race and geographic location but unique for each person and can vary significantly on a day-to-day basis. An average daily intake of 3–4 kg of food and drink is typical and some 5 L of fluids such as saliva, gastric juice, pancreatic juice, and other body liquids are added to the stomach contents during the day. The liquid–solid content within the stomach is a key factor in determining the fate of ingested material. Liquids and solids have separate and distinct emptying patterns.

Fig. 3 Reduction in peak plasma-concentration on second dose.

Following a meal, liquids empty first in a monoexponential pattern, before the gastric emptying of solids is initiated.

The stomach acts as sieve and a calorie regulator for the small intestine: As a consequence, meals that contain large fragments of food or are nutrient-dense will take longer to empty and hence will delay the passage of dose forms to the small intestine. Small tablets and pellets mix and empty from the stomach with food, but large nondisintegrating tablets are reliant upon the migrating myoelectric complex (MMC, the patterns of motor activity that act to move food through the gastrointestinal tract) in the fasted pattern of motility to empty them from the stomach. If the stomach is maintained in the fed state by continuous feeding then large dosage forms are retained in the stomach for that period.

Often patients are instructed to take their medication "with a meal," but instructions are never precise and this can be interpreted by the patient as taking the medication immediately before, during the meal, or just after the food. O'Reilly and co-workers (7) demonstrated that the initial-gastric emptying rate of multiparticulates dosed before a meal was faster than for those dosed during and after food.

Gastric emptying follows a circadian rhythm with slower emptying occurring in the afternoon compared with the morning. Such variation can be very marked: In a study by Ghoo and colleagues emptying of the solid phase of the meal decreased by over 50% when it was consumed in the evening (8). The fasted pattern of motility establishes itself overnight, as this is generally the longest period in which no food intake occurs. MMC occur with the greatest frequency in the early hours of the morning. Changes in MMCs probably produce the largest physiological variability in oral drug delivery.

FAT AND GASTRIC HOMOGENEITY

The fat content of food is one of, if not the, most important influence on the rate of gastric emptying. Within the stomach, fat will separate and form layers exposing the pyloric-duodenal region to different amounts of fat according to posture of the individual: erect, supine, prone, or lying on one side. Since digested fat has a marked inhibitory effect on gastric emptying, retardation will occur to varying degrees. Brown and colleagues found that fat quickly layered in the proximal stomach away from the pylorus, thus delaying gastric emptying (9). The delaying effect of lipid on gastric emptying is increased in the elderly (10).

If a dispersing phase such as minced meat is present, the fat will spread more uniformly. Edelbroek and colleagues labelled the fat phase of a meal with Tc-99m-thiocyanate,

to compare the gastric emptying and intragastric distribution of oil in a soup, based meal with and without minced beef (11). The emptying rate of oil in the oil/soupmeal was about twice that for oil consumed in the oil-soup-minced beef meal. These results show that major differences in the intra-gastric distribution of oil occur following incorporation of predispersed solids into the meal.

The gastric residence of a meal with identical composition will be prolonged if the fat content is used to fry the food rather than be ingested as the cold oil. The behavior of oils within the stomach is also affected by other constituents of the meal that are present. The effect of fat on gastric emptying and absorption of nutrients depends on the relation to the other components of the meal when the fat is consumed.

CARBOHYDRATE AND GASTRIC HOMOGENEITY

A study conducted in our laboratories looking at the absorption of a drug from low-volume, oil-filled soft gelatin capsules resulted in a variable bioavailability profile. Labelling the capsule with Tc-99m showed that formulation emptied immediately to the duodenum when given with fluid after a carbohydrate-based meal (sandwich). This unusual behavior was also investigated using magnetic resonance imaging (MRI). In this case, it was not necessary to label the formulation as the oil can be discriminated from the gastric contents using a T1, weighted FLASH sequence.

In the clinical trial, oil filled gelatin capsules were given immediately following a sandwich meal and the subjects were imaged in the prone position. Fig. 4 shows a cross-section of the body at the level of the upper abdomen: the agglomeration of the sandwich by the pyloric antrum into a "doughball" can be clearly seen. Following ingestion the meal is softened by mastication to aid swallowing. Although the maximum rate of salivary secretion is less than 5 ml min^{-1} , the bread is sufficiently softened. This moistened bolus is swallowed and the subsequent action of the stomach consolidates the mass. Eventually, the material is hydrated and the ball disperses. A small, almost buoyant gelatin capsule taken after the meal virtually bounces off the carbohydrate mass and exits from the stomach. This was confirmed by the gamma scintigraphic imaging study.

EFFECT OF POSTURE AND GRAVITY ON GASTRIC EMPTYING

Many studies have provided evidence that changes in posture can affect both the gastric emptying rates of

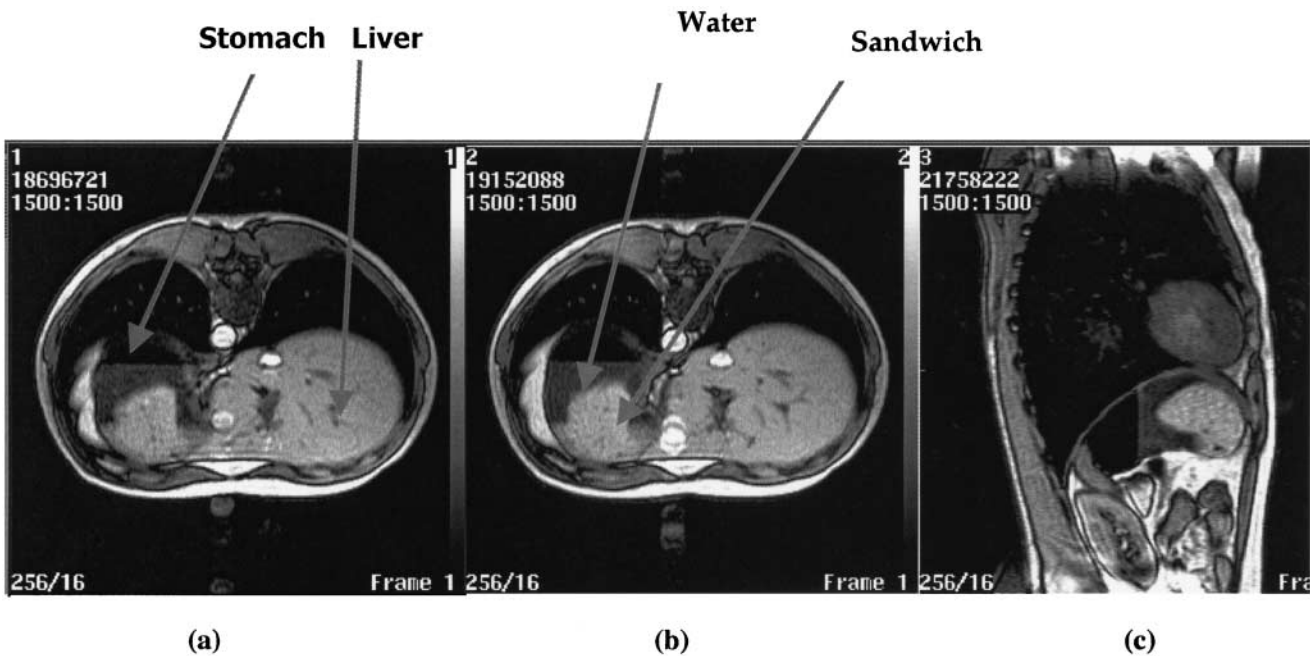

Fig. 4 MR images of the upper GI tract that show the compression of swallowed bread into a dough ball, viewed in (a) and (b) horizontal and (c) sagittal section.

materials and the absorption characteristics of drugs. Lying down decreases the rate of gastric emptying when compared with sitting and a combination of sitting and standing produces the most rapid gastric emptying. Bland, unbuffered liquids, and pellet formulations empty more slowly from the stomach when the subject is lying down compared with when he is upright or sitting erect. For floating formulations, such as raft-forming alginates, the buoyant raft empties faster than food in subjects lying on their left side or their backs and slower in subjects lying on their right side with the raft positioned in the greater curvature. When the subjects lay on their left side the raft was presented to the pylorus ahead of the meal and so emptied first.

The time to maximum plasma-concentration (T_{max}) of coadministered soluble paracetamol and nifedipine is significantly decreased when subjects are standing or lying on their right side compared with when they lie on their left side (12). These postures also resulted in a significantly higher peak plasma-concentration and area under the plasma-concentration–time curve of nifedipine.

GENDER AND PREGNANCY

Studies have examined the effect of gender and the menstrual cycle on gastrointestinal transit. Gastric

emptying of both solids and liquids is reported to be slower in women than men (13). Premenopausal women and postmenopausal women taking oestrogen and progesterone replacement were shown to have slower

Fig. 5 Mean plasma quinine concentrations following dosing with 50 mg of the dihydrochloride salt in the Pulsincap after treatment with codeine or lactulose. Error bar shows standard deviation.

gastric emptying of liquids than men. However, while premenopausal women and postmenopausal women taking hormone replacement therapy showed slower gastric emptying of liquid, postmenopausal women not taking hormones had a similar rate to men (14). It has been shown that females have faster emptying times when in the ovular stage of the menstrual cycle.

In women, pregnancy can drastically alter transit of drugs in certain regions of the gastrointestinal tract, although gastric emptying is not delayed (15). Nausea and vomiting occurs in 50–90% of pregnant women and may be so severe that hospitalization is required to prevent dehydration. Often pregnant women suffer from heartburn and constipation, which is attributed to decreased oesophageal sphincter pressure and impaired colonic motility (16).

SOCIAL EFFECTS—SMOKING AND ALCOHOL

Scintigraphic studies do not clarify the effect of smoking on transit. One study reported that smoking or chewing nicotine gum did not appear to affect oesophageal transit or the rate of liquid emptying; however, solid emptying was delayed (17). Other studies reported delayed emptying on both liquids and solids, which was associated with increased periods of retrograde intragastric movement of solids from distal to proximal stomach (18, 19). This suggests an initial impairment of antral function and/or a lack of antropyloroduodenal coordination once a contraction is initiated.

Strong alcoholic drinks such as whisky delay gastric emptying. A study showed that administration of beer or white wine significantly accelerated gastric emptying compared with ethanol of the same concentration (20). This suggests that the observed effect is due to compounds in the beer and white wine other than alcohol. Gastric emptying is delayed in 24% of chronic alcoholics (21). Finally, smoking delays the gastric emptying of alcohol indicating the possibilities of complex interactions due to social activities (22).

SMALL INTESTINAL ABSORPTION, FOOD, AND EXCIPIENTS

The small intestine is the main organ of digestion with specialized sites of nutrient uptake and drug absorption. The small intestine is a convoluted tube about 5 m in length with three regions: duodenum, jejunum, and ileum. During the fed phase the contractions serve to mix chyme with enzymes and digestive secretions, circulate the contents to

facilitate contact with the intestinal mucosa, and finally propel the contents towards the large bowel. The major areas in which digestion occurs are the jejunum and ileum, and digestion of proteins and fats is largely complete as the chyme enters the caecum. Small intestinal transit in man has been measured by a wide variety of techniques and is generally accepted to be around 4 h.

Components of food can alter drug absorption by affecting drug solubility. Recent findings suggest that drinks such as grapefruit juice can increase the bioavailability of certain drugs, by reducing presystemic intestinal metabolism (23). The solubility of the drug in the GI tract can also be enhanced when the drug is highly soluble in a coadministered food component. The solubility of dicumarol is five times higher in defatted milk than in buffer at 37°C. This increase in solubility and bioavailability is due to the main milk protein casein. Griseofulvin absorption is also enhanced by concomitant food intake, especially after ingestion of heavy fat meals. This enhanced bioavailability is probably due to the increased bile output and the prolonged gastric emptying.

Excipients such as mannitol can affect small intestinal transit, which in turn can affect the absorption of certain drugs. Oral solutions are rarely likely to fall short of bioequivalence relative to solid oral formulations, although during the development of a ranitidine effervescent oral solution dosage form containing sodium acid pyrophosphate (SAPP), a marked decrease in absorption was observed in the extent of ranitidine absorption from the liquid formulation relative to the conventional oral tablet. The formulation contained 150 mg ranitidine with 1132 mg SAPP together with 1.5 MBq ¹¹¹indium chloride solutions. Small intestinal transit time was decreased to 56% in the presence of the excipient. The rapid small intestinal transit associated with an excipient of a solution dosage form resulted in a decreased extent of ranitidine absorption (24).

Intestinal transit rate is highly dependent on the motility state of the GI tract either fasted or fed partly due to the higher viscosity of chyme in the fed state. Blair and co-workers conducted a study in 20 men (energy intake 1272–5342 kcal/day) and found that higher calorific intake was associated with faster transit (25). Exercise in moderation appears to have no effect on transit.

THE COLONIC ENVIRONMENT

By the end of the small intestine, deposition is almost complete and there is no need for intestinal secretions to aid assimilation. The principal role of the colon is to resorb

water and reclaim sodium; however, complex carbohydrate components of vegetable origin have nutritional value but are relatively resistant to attack from intestinal secretion. In the caecum, a complex bacterial environment digests the soluble, fermentable carbohydrates to yield short-chain fatty acids, which are assimilated into the systemic circulation by the colon, together with vitamin K released from the plant material.

The presence of the complex carbohydrates provides the environment with a viscous hydrogel structure; water removal gradually yields a mass of bacteria bound by undigested carbohydrates (celluloses) to form the stool. The presence of a hydrogel softens the mass and also provides water for dissolution. Carbon dioxide release is also a fermentation product, and if the redox potential is sufficiently low, bacteria can produce methane and hydrogen that can be detected in the breath particularly after the ingestion of pulses. In the upright position, the gas will rise to the transverse colon: It is estimated that an adult produces approximately 2–3 L per day on 20 g fermentable fibre (most of which is eliminated in the breath) (26). The presence of large volumes of gas appears to restrict the availability of water past the hepatic flexure, and the consequences of this must be carefully considered.

Residence of dosage forms is approximately 10–12 h in the proximal colon and 12 h in the descending and rectosigmoid colon regions, giving a whole colon transit time of 24–48 h. The relative residence time in the segments of the large bowel is highly dependent upon feeding pattern. Administration of a midday meal to a previously fasted subject may produce dramatic movement, shifting dosage forms from the ascending to the descending colon. Dietary fibre in the form of bran, whole-meal bread, and fruit and vegetables reduces colonic transit time but increases faecal weight by acting as a substrate for colonic bacterial metabolism. For example, an additional 20 g/day of bran increases faecal weight by 127% and decreases mean transit time from 73 ± 24 to 43 ± 7 h (27). However, the same quantity of fibre given in the form of cabbage, carrot, or apple produced a smaller effect.

EFFECTS OF CHANGES TO THE COLONIC ENVIRONMENT

Administration of osmotic laxatives such as lactulose to healthy subjects increases defaecation frequency, producing a reversible syndrome that mimics irritable bowel syndrome. Administration of 20 ml lactulose three times per day creates a more fluid environment as indicated by increased stool water content (28). To examine the effect

of such an environment on drug delivery we administered pulse release units (Pulsincap) containing quinine dihydrochloride (50 mg) following treatment with lactulose for 3 days (29).

Plasma-concentration-time profiles following lactulose treatment showed a faster T_{\max} , a higher C_{\max} , and an increased AUC indicating significantly improved absorption. These data correlated with a higher dispersion score for the marker indicating that the water content of the colon plays an important part in determining the extent of absorption in man. This will be especially important for pulsed release systems in which the exterior is covered by an impermeable coat. The sluggish mixing and the low availability of water past the ascending colon could compromise efficient release of the drug encapsulated in the system.

EFFECTS OF DISEASE ON GASTROINTESTINAL TRANSIT

Esophageal transit time is adversely affected by various disease states, for example, achalasia (30) scleroderma, oesophageal carcinoma, Barrett's oesophagus, cervical vertebropathy (31), left side heart enlargement, and reflux oesophagitis. Abnormalities in oesophageal function can occur as a result of a variety of disease such as chronic alcoholism and diabetes mellitus (32).

Diseases that affect gastric motility and emptying are predominantly diseases of the gastrointestinal tract itself, although diseases such as diabetes that produce neuropathy can also alter transit. Diseases associated with accelerated transit can reduce the bioavailability of drugs delivered in a controlled-release formulation and conversely diseases that slow transit can enhance absorption. Stasis or stagnation at a particular site is always of concern since high local concentrations of drug may result. Inhibition of motility, especially of the stomach, is widely recognized as a consequence of many acute illnesses such as severe pain of any origin, trauma, major infections, and metabolic disturbances.

Some diseases only affect one of the phases of gastric emptying. Generally, duodenal ulcers produce accelerated emptying while gastric ulcers reduce antral motility, producing normal emptying of liquids but delayed emptying of solids. Emptying of a solid meal is slowed in patients with pernicious anaemia and atrophic gastritis but in achlorhydric patients liquids empty rapidly.

Gastro-oesophageal reflux is an extremely common disease affecting between 10 and 20% of the general population, although it is speculated that the incidence is

considerably higher since a large proportion of sufferers self-medicate. The effect of this disease on gastric emptying is unclear since some studies report no effect on the emptying of liquids or mixed meals whilst others demonstrate a delay. It is possible that the emptying of solids in a mixed meal is selectively delayed, suggesting impaired antral motility. This would lead to a greater difference in emptying among liquids, pellets, and tablets than in normal subjects.

There are conflicting reports as to the effect of obesity on gastrointestinal transit. Some studies show no effect, whilst others report delayed emptying of solids particularly in men. This phenomenon is not reversed after significant weight loss. The eating disorders anorexia nervosa produces both delayed solid and liquid emptying (33). Voluntary suppression of defecation also decreases gastric emptying rate (34). The effects of gastrointestinal disease on dosage form performance have recently been reviewed by Milovic and Stein; the reader is referred to this review for further information (35).

Diarrhea and constipation are associated with many illnesses and always produce concern to the effectiveness of therapeutic agents. Like gastro-oesophageal reflux, the aetiology of these conditions is diverse and hence the effect on transit will vary. For example, in a group of constipated patients, a scintigraphic study using a water-soluble marker demonstrated a rapid and diffuse spread through the colon, 5/37 showed normal transit, 26/37 showed that the major site of hold-up was the transverse colon, and the splenic flexure and 6/37 the hold-up was in the descending and rectosigmoid colon (36). Prodrugs such as sulphasalazine, which rely on colonic bacteria to release the active moiety, will be affected by diarrhea (37).

Diseases such as diabetes, which have diverse complications, can produce different changes in gastrointestinal motility in different patients. Delayed oesophageal transit is common, although it does not tend to produce clinically significant problems. However, diabetic gastroparesis is a problem. These patients demonstrate reduced postprandial antral times compared with diabetic-without this complication, although overall transit is not different. There was no correlation among disturbed gastric clearance, impaired gall bladder contraction, and prolonged colonic transit time in the patients with cardiovascular autonomic neuropathy nor was there a correlation between any disturbed motor function and age or duration of diabetes (38).

Patients with cystic fibrosis require pancreatic enzyme supplements to aid food digestion. A recent investigation in which enteric coated enzyme pellets were labelled with ¹¹¹indium and given to patients with a pancake meal

labelled with Tc-99m tin colloid showed that the pellets passed through the intestine ahead of food (39). These data suggest that the incorrect delivery of this enzyme might be responsible for malabsorption and the development of strictures in the proximal colon caused by the high-dose supplements reaching this region before the food.

pH IN HEALTH AND DISEASE

Food affects bulk pH in the stomach by dilution, buffering, and stimulating acid secretion. In the colon, pH is affected by meals containing a high proportion of fermentable fibre. The greatest secretory activity occurs in the stomach within the first hour of eating and the volume of gastric juices produced may be up to twice that of the meal. Studies using a triple pH electrode show that the peak buffering effects of food occurs within 30 min of eating with recorded variations in the stomach varying from pH 2 to around 4.5 (40). Even small volumes of water taken with medications can cause a temporary rise in pH due to neutralization effects on the residual acid.

Content of the meal also affects gastric pH. For example, a pure carbohydrate meal has no detectable effect on acidity (41), whereas a high protein meal matched for calorific content confirming that it is not the protein but its digestion products, the peptides, and amino acids, which are the potent stimulators of acid secretion. A liquid meal, rather than a mixed phase meal, with a balance of carbohydrate and protein has a strong buffering effect but the pH falls rapidly as the liquid is emptied.

Some research workers have found that the basal gastric pH can be surprisingly high. Spontaneous achlorhydria has been observed in healthy subjects during which they have temporary periods of profound reduction in acid secretion and may have complete anacidity (42, 43).

The pH in the small intestine is less variable than the stomach or colon and is in the region of 5.0–6.5, rising slowly along its length. The mean pH in the right colon is 6.4 rising to 6.6 and 7.0 in the transverse, and descending colon, respectively. The presence of fermentable dietary fibre produces a reduction in both viscosity and pH in the colon (44). Recent studies in Japan suggest that patients with Crohn's disease, whether active or in remission, have wider fluctuations in colonic pH, and values in the right and left colon are much lower than would be expected on the basis of control subjects (45).

A circadian rhythm of basal gastric acidity is known to occur with acid output being highest in the evening and lowest in the morning. The daytime patterns of gastric pH vary greatly between individuals, in part due to

the differences in the composition of meals, the physiological responses of acid secretion and gastric emptying provoked postprandially; however, it has been found that the nocturnal patterns of gastric acidity are very similar with very low pH between midnight and early morning (41). The later in the day the evening meal is taken, the later the nocturnal peak of acidity occurs (46). It is, therefore, important to standardize the time for the evening meal when comparing the nocturnal effects of antisecretory drugs.

pH AND GENDER

There is a sex-related difference in human gastric acid secretion. Healthy women secrete significantly less basal and pentagastrin-stimulated acid than men with a median 24 h integrated acidity of 485 mmol h^{-1} versus 842 mmol h^{-1} . In a sample of 365 healthy subjects, the average basal pH was 2.16 ± 0.09 for men and 2.79 ± 0.18 in women (47).

pH AND AGE

It has always been assumed that gastric acid secretion decreased with age, however, a recent study has demonstrated that a group of healthy subjects with a mean age of 51 years (range 44–71 years) had a higher basal acid production than a group with a mean age of 33 years (range 23–42 years) (48). The age, related increase in secretion was greater in men than women but it was not correlated with height, weight, body surface area, or fat-free body mass or by the increased incidence of *Helicobacter pylori* infection.

Very few data are available on gastrointestinal pH in children. In 12 healthy subjects aged 8–14 years, the mean gastric pH was 1.5 and duodenal pH was 6.4, but this gradually rose in the small intestine reaching a peak value of 7.4 in the distal ileum (49). The pH dropped to 5.9 as the pH radiotelemetry capsule entered the caecum but increased to 6.5 in the rectum. The median gastric residence time of the telemetry capsule was 1.1 h, small intestinal transit time was 7.5 h, and colonic transit time was 17.2 h.

CONCLUDING REMARKS

It is clear that numerous physiological factors and disease states alter the gastrointestinal environment and affect

the transit and absorption of a formulation through the gastrointestinal tract. An appreciation of these physiological factors is essential for the optimization of clinical studies. However, high individual variability will remain the major challenge in clinical trial design.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the permission to use data generated in clinical trials in association with industry and clinical services. In particular, we thank Dr. M Frier and Professor A.C. Perkins (Queen's Medical Centre Nottingham), Dr. Tim Grattan (SB Healthcare), Dr. Richard Dansereau (Proctor & Gamble Pharmaceuticals Inc.), and Dr. J. Foster (Western Infirmary, Glasgow).

INTRODUCTION

A pilot plant design should support three key strategic objectives:

- Formulation and process development.
- Clinical supply manufacture.
- Technology evaluation, scale-up, and transfer.

Integration of these objectives serves to maximize product development, speed, and efficiency. The pilot plant is a “hybrid” clinical manufacturing and development facility, which integrates early development activities, clinical supply manufacture, technology evaluation, scale-up, and transfer to production sites. The manufacture of clinical supplies is an integral part of the development process. As the clinical program requirements increase, batch size increases, and critical formulation and process performance information can be obtained during manufacturing scale-up. This information and experience contribute to smooth and efficient production transfer.

Specific design layout depends on a number of factors. The design may be constrained if the construction entails renovation or conversion of an existing building compared to designing a pilot plant on a new site. The various technologies and systems, such as fluid-bed granulators, microwave processors, lyophilizers, water systems, and dust collectors, have specific design requirements and constraints that require special consideration. Location of a new facility must be evaluated early in the program. This evaluation is essential in determining site–location factors, such as proximity to development, production, clinical packaging, and warehouse, as well as support staff considerations, such as quality assurance (QA), quality control (QC), validation, maintenance, calibration, microbiology, and other functions.

The final design should result in a facility that supports the key strategic objectives, is functional, and has

low maintenance and operating costs. The interaction between the design firm, corporate engineering, and the client is central to an operational design and end user satisfaction. In addition to the architects and engineers, the core multidisciplinary team should include personnel from QA, QC, validation, maintenance, calibration, pilot plant operations, formulation development, information technology, purchasing, environmental health, and safety. Security, telecommunications, purchasing, and the insurance carrier should assign members to the project who can serve as resources for specific needs.

A design firm should be chosen according to the range of services offered and experience in designing good manufacturing practices (GMPs) facilities. Selecting a firm that offers architectural, engineering, and construction consulting, as well as life-safety services is recommended. A pilot plant is a “hybrid” clinical manufacturing and development facility, and overdesigning for waste treatment, safety, and fire codes is highly likely if the proper experience and interpretation of codes and operational aspects are lacking. Visiting facilities the firm has designed is useful to examine the quality of past designs and to find out how well the firm fulfilled its obligations and dealt with problems. Including key design firm members in the contract is highly recommended. Experienced design engineers and a staff with a proven track record are considered to be most critical.

Early involvement of the Food and Drug Administration (FDA) in reviewing the facility design is advised. This allows the most current FDA interpretation of GMPs to be incorporated into the facility design. As the design is being finalized, it should be presented to the local, district, and Washington FDA offices for review and critique. Discussions concerning material flow, personnel flow, building surfaces, air classification, and the validation master plan may be a useful means of presenting the design and opening a dialogue with the FDA. Extending an invitation to the local and district FDA personnel to

visit the facility during various phases of construction is also recommended.

STRATEGIC OBJECTIVES

Formulation and Process Development

Strategic decisions regarding the dosage forms to be developed in the pilot plant and the technologies employed significantly affect the design.^[1] These strategic decisions are often based on current production technology, dosage form development, and assessment of potential delivery system requirements to support future line extensions and the pipeline of new chemical entities (NCEs). An assessment of the proportional utilization of the various technologies and anticipated processes is important in deciding how much space to allocate to each in the layout.^[2] During the transition from the development scale to pilot scale to full-scale manufacturing, identification and control of critical component, formulation, and process variables are essential for final production. The facility and equipment should be able to capture critical process information. The more sophisticated the technology, the greater the need to control and monitor critical parameters. It may also be desirable to monitor and control these parameters from remote locations.

Clinical Supply Manufacture

To manufacture clinical supplies, GMP-compliance considerations must be the basis of the design features of the pilot plant.^[3] Integrated validation plans for the equipment and facility should be available before the basis of design is finalized. These design features must meet safety and environmental facility requirements to handle compounds for which only marginal information is available regarding potential toxicity, potency, and physical–chemical properties. Highly potent compounds need to be handled and manufactured in an isolated and contained environment requiring special design controls.^[4]

Clinical supply manufacture should be viewed as an integral part of the product development process. As the program requirements grow, the increased clinical trial demand needs to be met by increased manufacturing capacity. Critical formulation and process performance information is gained during the scale-up of clinical batches. Often there is a shortage of drug substance, and the first opportunity for the formulation scientist to scale-up a product is when clinical supply requirements justify the need.

Pharmaco-economic studies that evaluate quality of life and other medical outcome criteria enroll thousands of patients and require millions of dosage units. These larger batch requirements can be manufactured in production or can be outsourced to a contract resource organization (CRO). In either case, a certain degree of control and flexibility is given up, which may slow clinical programs. Having direct access and control to a clinical manufacturing facility with large scale capability allows flexibility and short turnaround times to meet clinical demands. During facility design, strategic decisions regarding manufacturing capacity based on clinical needs significantly impact space and equipment capacity.^[1] Table 1 shows batch sizes and production capacity based on typical unit weights that could be used in determining design objectives.

Technology Evaluation, Scale-Up, and Transfer

Flexibility in facility design can better accommodate new technology evaluation. The technology may be new to the company or novel to the industry and offers advantages that current production and pilot plant facilities lack. New technologies may increase production speed, and provide continuous processing, maintenance, scale-up, cleaning, and containment improvement. Novel technologies may include evaluation of the manufacture of novel delivery systems or processes. In any case, a flexible pilot plant design (utilities and space) gives the development scientist

Table 1 Maximum batch manufacturing capabilities based on typical unit weights

Technology	Batch capacity (kg)	Units per batch
Solids, 500 mg/unit	200	400,000
	20	40,000
	5	10,000
Semisolids, 50 g/unit	500	10,000
	100	2,000
	10	200
Liquids, 100 mL/unit	1000	10,000
	100	2,000
	10	100
Parenteral, 10 mL/unit	250	25,000
	50	5,000
	10	1,000
Aerosol, 20 g/unit	250	25,000
	100	5,000
	10	500

and technical operations personnel the opportunity to collaborate in technology evaluation.^[5]

Critical formulation and process performance information can also be obtained in the pilot plant.^[6] As the clinical supply quantity requirements increase and larger batches are needed, operations can be scaled into larger equipment of the same or similar operating principles. This makes it possible to identify critical process variables and ranges and to study the effect of scale. Fig. 1 shows fluid-bed granulator–dryers, and Fig. 2 shows coating pans of different sizes. The closer the pilot plant equipment resembles production equipment with respect to design and scale, the fewer trials, often with costly drug substance, are necessary when transferring the process to production. Large-scale equipment in the pilot plant should be at least 10% of the capacity used in production, but ideally should approach 25–100% of the capacity of full-scale equipment.

Typically, a combination of engineering models, statistically designed experiments, and regression models can be used to define the manufacturing process with

respect to process parameters and ranges to ensure adequate control of the full scale process.^[7] The scaling experience improves the understanding of the product and process scale parameters. This knowledge contributes to a smooth and expedient production transfer, providing a strong scientific rationale, which leads to credible new drug applications (NDAs) and FDA pre-approval inspections (PAIs).

DESIGN AND GMP-COMPLIANCE CONSIDERATIONS

Layout

In designing the facility and its layout, the impact on GMPs must be kept in mind. The layout should address the need for flexibility, restricted access, personnel flow, and material flow.

Product development starts with many unknowns that eventually, through well-designed development programs,

Fig. 1 Fluid-bed granulator driers of 1, 5, and 50 kg capacity, which provide flexible clinical supplies manufacturing capacity and can be used to understand critical process variables and scaling parameters.

Fig. 2 Coating pans of 1, 15, and 150 kg capacity.

result in a value-added product. Because of these unknowns, it is difficult to predict exactly what kind of physical facilities will be required. Thus, there is a need to incorporate as much flexibility into the design as possible. The desired flexibility can be achieved in a number of ways. For example, fixed process equipment is kept to a minimum, while portable equipment is installed whenever possible. Movement of portable equipment is made easier by wide corridors and 10 ft (3 m) door heights. In addition, the process rooms can be designed for multipurpose use, which adds flexibility. The concept of multipurpose process rooms determines the degree of flexibility desired for utilities, such as the range of power supplies and plant systems including dust collection, vacuum cleaning, water, static grounding, and compressed air.

Restricted access and personnel flow affect the layout. The size of the facility and anticipated nominal daily personnel level determine the size of restroom, locker, gowning, and shower areas. The types of garments worn by personnel in the pilot plant should be specified and provisions made for their cleaning, disposal, and storage. Gowning and degowning procedures should be investigated and formalized.

Material receipt, sampling, and quarantine processes should be well planned. The material and components used in manufacturing clinical supplies should enter the facility through a controlled access area. Sampling and quarantine procedures affect the facility layout and design. Special precautions for sampling potent (highly active) compounds should be considered. This may require the use

of specially designed rooms that include air locks, gowning areas, and isolation sampling methods. Delivery and shipping personnel should have access restricted to the receiving and dock area. A receiving office should be located immediately adjacent to the actual receiving area. A restroom, telephone, and seating area for the transportation personnel are other design options. The type of lift trucks used requires certain clearance heights and widths. Battery-operated lift trucks require space for charging the equipment, and ventilation requirements must be evaluated. Receipt, sampling, and quarantine storage of flammable solvents require special consideration such as location, explosion-proof lighting, and electrical connections. Solvent-dispensing practices and spill containment procedures are important parameters. Space is required for the temporary holding of flammable waste products as well as other waste.

The warehouse layout depends on the manufacturing scale, type of products, and storage requirements. Temperature and relative humidity set points and ranges should be defined, as well as special storage conditions, which require refrigerators, freezers, and controlled access. Storage capacity and space constraints may dictate high-density shelving and determine pallet-stacking height. Storage within the facility is best, but off-site storage for medium-to long-term supplies or large quantity purchases may be a more cost-effective alternative. The method of inventory identification, status, and the selection of lift truck size determine the design and capacity of the receiving, shipping, and warehouse areas. Systems that meet GMP iden-

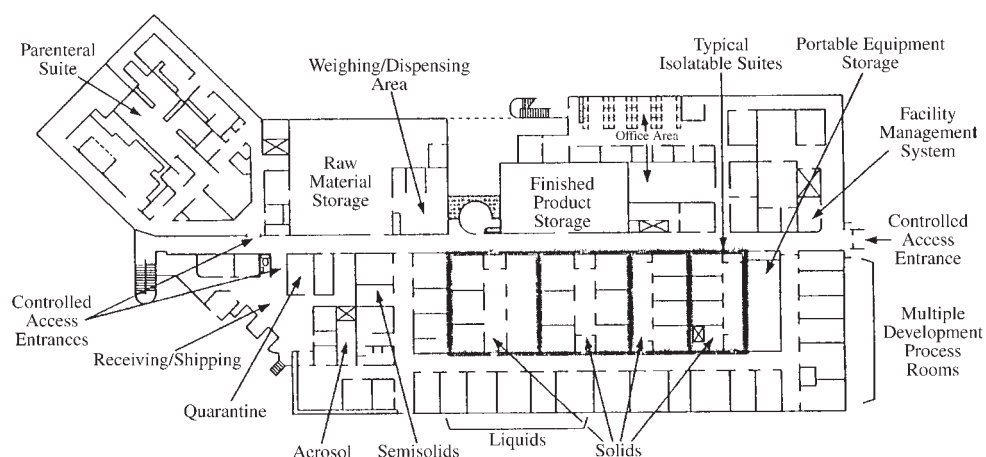

Fig. 3 A pilot plant layout.

tification and status requirements without requiring storage of material of the same status in the same location maximize space utilization.

Fig. 3 shows a pilot plant layout with restricted personnel access. This design would support the development and clinical manufacture of solid dosage forms, liquids, semisolids, aerosols, and sterile products. Multipurpose rooms are incorporated in each area to maximize the use of portable equipment, and scale factors similar to those shown in Table 1 are employed. Isolation suites are indicated in the manufacturing area; their purpose and design are discussed in more detail later. The sterile area is isolated from the main corridor by the interior corridor design. At the far left, the main corridor provides access for future facility expansion, if necessary.

Construction

As a multipurpose, multiproduct facility, the walls, ceilings, and floors need to be constructed of readily

cleanable surfaces. Radial joints at the wall, ceiling, and floor junction facilitate cleaning and wash-down. Cabinetry should be of nonporous construction and have slanted tops to minimize dust collection and aid in cleaning.

Table 2 lists a number of available, acceptable, wall and ceiling material compositions and their relative attributes of purchase and installation costs, cleanability, durability, resilience, and ease of repair. The connections between the wall and window frames, doorframes, and the floor need to be carefully constructed to prevent moisture damage and enhance cleanability. Dry-wall fiberglass mats painted with epoxy provide durable, cleanable surfaces at a lower cost than many other options.

Floor selection criteria should include chemical resistance, stain resistance, scuff and marring resistance, ability to radius cove, durability, esthetics, and ease of maintenance and repair. Table 3 lists several floor compositions and selection criteria. Special areas may require static dissipative or conductive flooring in order to minimize explosion potential with flammable material.

Table 2 Ceiling and Wall Material Compositions^a

Material	Cost of Purchase and Installation	Cleanability	Durability	Resiliency	Ease of Repair
Dry-wall with epoxy paint	□	□	■	■	□

^a Key: □ better; ▣ intermediate; ■ worse

Metal or reinforced fiberglass doors and doorframes are most desirable. Doorframes that terminate at the top of the cove base allow easy cleaning. Top locking of the inactive door is preferred for dual-panel doors because this eliminates the need for floor penetrations and cleaning concerns. The door closures should be readily cleanable.

Light fixtures should be washable and allow for easy maintenance. Frames are often sealed at the ceiling surface to prevent moisture intrusion and microbiologic growth. Lighting levels in the process areas should be specified in the design. Switches in the hallway or automatic switches facilitate cleaning operations and eliminate the need for expensive explosion-proof devices.

The need for floor drains should be considered, as well as the ability to collect wastewater for treatment or incineration. If floor drains are installed, the floors should slope toward the drain from all directions. Drain cover materials should also be evaluated with regard to quality, ease of sanitation, and cleaning. Fig. 4 shows a multi-purpose room with an easily cleaned floor, dry-wall fiberglass mat with epoxy-painted walls, floor drain, and utility panel. This room also has self-contained hot- and cold-water wash-down capability.

Building Systems and Utilities

The following building systems and utilities need to be addressed at the design phase: HVAC (heating, ventilation, and air conditioning), pharmaceutical water systems, compressed gases (nitrogen, air, respiratory air), electrical outlets with various voltages, dust collection, vacuum cleaning, communication systems, emergency back-up power generation, environmental monitoring, and control of temperature, relative humidity, and differential pressure. The selection and extent to which these systems and utilities are included in the pilot plant design depend on the pharmaceutical product produced, e.g., oral solid vs. sterile dosage forms, and the technologies chosen.^[8,9]

The pilot plant HVAC system must be suitable to consistently produce a quality product and flexible enough to accommodate different process areas and dosage forms. Although not intended for universal application, typical HVAC requirements have been developed for the process areas in a pilot plant.^[10] Different process areas might include manufacturing areas such as dry, liquid, and sterile processing, general support areas of pharmacy, in-process and final storage, and general laboratories including QC and inspection. Other HVAC design considerations might include noise level in occupied spaces, determination of allowable drift before recalibration of sensors and controllers, level of acceptable airborne contamination, and maintenance.

If the most critical utilities used in the pharmaceutical pilot plant are those that come in contact with the product, then water is most likely at the top of the list. Water is commonly used during processing of the product and also for cleaning of equipment and process areas. Water quality can be divided into two subcategories. The first is compendial, of which there are two types, USP purified water and USP water for injection (WFI). There are many different approaches for designing compendial water systems. These systems are, in general, among the most difficult building utilities to commission and maintain. Critical assessment of the volume demand and number of use points define the system size. Smaller systems are easier to commission and maintain and minimize the number of use points. The quality of feed water should be assessed to confirm that the water treatment could handle seasonal variations. Excellent resources are available regarding the design, construction, and operation of compendial water systems, including clean steam.^[11]

The second category of water is noncompendial. Noncompendial water, often referred to as potable water, is generally used for initial rinsing and cleaning of process rooms and equipment. This water should meet the Public Health Services Drinking Water Standards.^[10]

Fig. 4 Multipurpose room with an easily cleanable covered terrazzo floor, dry-wall fiberglass mat with epoxy-painted walls, floor drain, and utility panel. The room has a self-contained hot and cold water wash-down capability.

Noncompensial water is also used in the laboratory environment and is usually referred to by the final treatment step, e.g., reverse osmosis (RO) water and deionized (DI) water.

Provisions should be considered for compressed gases, such as nitrogen, which can be used in the presence of highly explosive dust or solvents as an inert gas blanket or as the energy source in fluid-air micronizers. Compressed air is often used in explosion-proof environments to operate pneumatic switches and as the power source for mixers. Respiratory air may be needed for work with highly active compounds. Compressed gases and respiratory air should be free of oil or other contaminants and meet stringent particulate requirements. Piping for gas utilities may require special consideration during fabrication to control particulate matter such as welding under inert atmosphere. Point of use filters can be used for other process gases such as nitrogen and carbon dioxide.^[10] Respiratory airdrops should be placed at locations that provide easy access to the user. The system can be designed with “quick disconnections” that are keyed and color-coded for each type of compressed gas to prevent inadvertent or inappropriate use.

The service and cleaning of dust-collection and vacuum-cleaning units deserves special attention. Isolated “bag houses” designed with breathing air, decontamination showers, and floor drains with shunt valves that allow

waste water to be pretreated should be considered for dealing with highly active compounds.

A building monitoring and control system can range from simple to complex, depending on the degree of control desired. The simplest level can be used for monitoring and controlling air temperature and relative humidity. Other areas where monitoring and control may be desirable include exhaust duct monitoring for lower explosives limits in solvent processes, differential room pressures, differential pressure across high efficiency particulate air (HEPA) filters, conductivity in USP-WFI water systems, compressed air–nitrogen pressures to detect leaks, oxygen monitoring in areas using nitrogen, chilled process water and clean steam pressure, a synchronized clock system, and environment particulate monitoring in parenteral areas. A system for monitoring and archiving critical environmental and utilities data is shown in Fig. 5. This system allows routine monitoring of critical instrument alarms and provides continuous updates of environmental conditions within and outside the facility. The system identifies the specific process room number and the temperature, percent relative humidity, and differential pressure status. The information can be archived for retrieval during an FDA inspection. Custom report generation allows data arrangement for easy review.

Aseptic Area Partial View

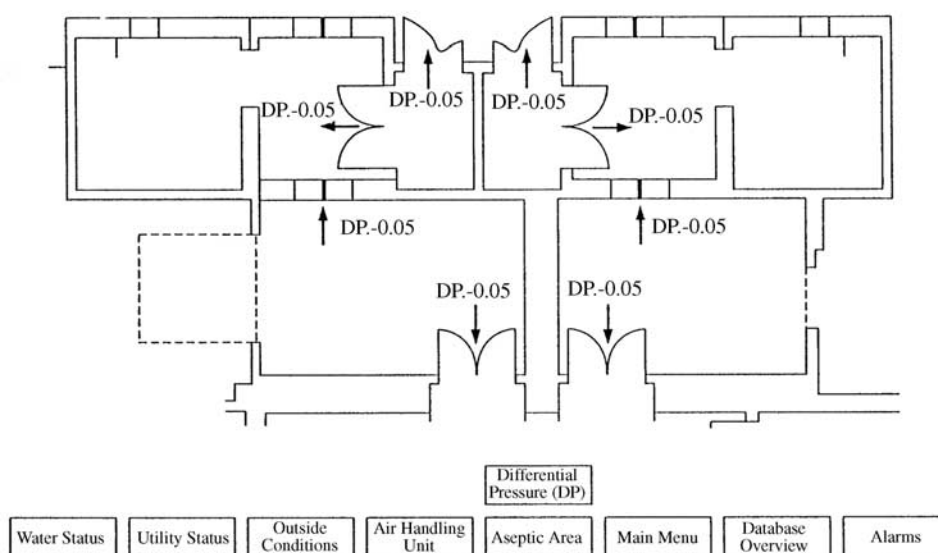

Fig. 5 Facility monitoring and control room (top) and operator interface screen with aseptic area differential pressure readings (bottom). Features that can be monitored via touch screen from the control room include water status, utility status, outside conditions, air-handling units, and process areas in nonsterile and sterile locations.

Service access to system utilities is an important design consideration. Routine calibration, maintenance, and repair are integral parts of maintaining a GMP facility. Areas to store critical spare parts and supplies should be included.

Equipment

Equipment can be viewed as fixed or portable; both types should be easy to clean and maintain. Fixed equipment has

the largest impact on the building design. Special considerations such as explosion proofing, explosion relief, explosion containment, and the need for uninterrupted power supply should be identified early in the design process. Dedicated process air handlers may be required for fluid-bed granulator-dryers and tablet coaters. Clean-in-place (CIP) systems may require special attention. Storage of portable equipment, operating supplies, and spare parts is important. The storage area for portable equipment should be placed strategically to complement the material and personnel flow plans.

SAFETY AND ENVIRONMENTAL CONSIDERATIONS

Emergencies

Emergency communication notification systems, telephones, smoke and gas detectors, and sprinkler systems need to meet state and corporate fire and emergency codes, as well as insurer's requirements.^[12] Specific processes or technologies may require a wet or pre-action sprinkler system. Local code, corporate standards, or site preference determine the specific type chosen. Consideration should be given to the manufacturing processes performed in the area. In a multipurpose facility, the issues should be addressed using a "worst case" scenario. Pre-action (dry piping) systems may be desirable in a sterile product area where accidental leakage could lead to microbiological contamination and area shutdown. System drainage is important and draining procedures should be developed for accidental loss of air pressure within the piping. Alternative methods of fire prevention, such as fire-resistant construction, may be specified to eliminate the need for sprinkler systems.^[13] Windows in the process rooms and hallways can be aligned in such a way as to allow observation of operators from several different vantage points. Safety glass can be used to meet fire codes. Phones and intercom systems can be used to enhance communications between operators, support staff, and management. The selection of communication systems should be based on ease of use and cleanliness.

An emergency notification system should be designed to attract the attention of operators who may be wearing noise protection or breathing-air suits. Visual flashing lights and a loud siren intercom system are simple yet effective means of notifying employees of an emergency situation. Pressurization of emergency exits may be needed when an emergency alarm is actuated.^[12] "Man-down" type of emergency systems may also warrant considerations.

Environmental Discharges

Pilot plant discharges into the environment must comply with local, state, and federal regulations. Of particular concern are facilities that use organic solvents for granulating or coating processes. Atmospheric discharges from equipment such as incinerators, scrubbers, and dust collectors require permits from state authorities and must comply with the federal Clean Air Act.^[14] Permits are required for the generation, treatment, and recycling of hazardous wastes and emissions.^[14] Liquid discharges

into the local water system must meet limits set by the federal Clean Water Act, as well as any other state and local regulations.^[15] Isolation and pretreatment or an alternate means of disposal of wastewater will likely be required if highly potent or toxic compounds are to be processed.

Handling and Prevention of Deflagrations and Explosions

The potential for explosions is an ongoing concern in pharmaceutical operations. Many pharmaceutical dusts, airborne in sufficient concentration, are capable of propagating a flame (deflagration) in the presence of oxygen and an ignition source.^[16] Hybrid mixtures of dust and flammable vapors, such as may be encountered with solvent-based granulating or coating, can create exceptionally explosive conditions. Explosion prevention of solvent storage and dispensing areas requires special attention to ventilation, grounding, and dispensing methods. Static grounding and electrical outlets rated for hazardous environments should be included in all processing areas to eliminate potential ignition sources. In many circumstances, the potential for generating a deflagration is unavoidable, so the pilot plant design must include methods for suppressing, containing, isolating, or venting an explosion in such a way as to protect operators and minimize damage to the equipment and facility. The most commonly used method, explosion venting, incorporates a blowoff panel in the equipment or ductwork to safely vent the explosion to the exterior of the plant. An explosion suppression system should be used if any dust collectors are to be placed within the interior of the building or if toxic materials, which cannot be vented outside the building, are to be used.^a For additional information refer to the National Fire Protection Association (NFPA) Codes 68, 69, 318, 497, and 654.^[17-21]

Handling of Highly Potent or Toxic Compounds

Building design, equipment design, and the use of physical barriers and personal protective equipment (PPE) are the primary methods of maintaining a safe environment, inside and outside the facility, while handling highly potent or toxic compounds. When designing a pilot plant facility to be used for handling highly potent and/or toxic compounds, numerous criteria must be considered:

^a<http://www.fike.com/epvent.htm> (accessed November 2001).

- Unit operations to be performed.
- Range of batch sizes to be processed.
- Capital expenditures and operational costs.
- Anticipated occupational exposure limits (OELs) to be encountered.
- Employee safety and ergonomics.
- Material, equipment, and personnel flow.
- GMP requirements.
- Cross-contamination risks.
- Flexibility of the facility.

Containment of highly potent or toxic compounds is most effectively accomplished by using a physical barrier such as a glove box. A product or process that can be isolated within a physical barrier can significantly reduce the need for air handling capacity, minimize cross-contamination potential, and reduce employee exposure.^[22]

In situations where it is not feasible to depend only on physical barriers, an isolation suite can be designed for working with these materials. Air locks and rooms

that have negative differential pressure to the main hallways are required, as well as HEPA-filtered inlet air and double-HEPA-filtered exhaust air. An uninterrupted power supply should be connected to the exhaust air handler to maintain a negative differential pressure if the suite is in operation during a power outage. If the exhaust air handler fails, all plant air handlers should be programmed to automatically turn off to minimize the potential for a positive differential pressure to develop. Each isolation suite may require a dedicated HVAC system.^[23]

The isolation suites can be designed with respiratory air capability. The air suits should be cleanable, safe, comfortable, and available in a variety of sizes. The respiratory air compressor should be placed on an uninterruptable power system.

Provisions should be made for water decontamination showers and wastewater diversion. The decontamination showers and rooms can have drains and shunts to divert wastewater and treat it, if necessary, before it is sent to the general waste stream. Fig. 6 shows an operator gowned in

Fig. 6 Operator gowned in a breathing-air suit and standing in the doorway of decontamination shower.

Fig. 7 Aerosol isolation suite where manufacture takes place in a totally enclosed system with clean-in-place capability. The operator is gowned in a washable suit and is wearing a powered-air-purifying respirator.

a breathing-air suit and standing in the doorway of a water decontamination shower, which can be programmed to deliver a water wash followed by drying air for a predetermined cycle time.

Fig. 7 illustrates the use of facility design, equipment design, and personnel protection. The picture is taken from an aerosol isolation suite where the manufacturing process is performed in a totally enclosed system with CIP capability. The operator is shown in a washable Tyvek[®] suit, and is wearing a battery-powered, air-purifying respirator.

The weighing, dispensing, sampling, and vacuum dust-collection areas for highly active materials require special design considerations. Fig. 8 shows a weighing and dispensing room. The airflow has been validated by video smoke and tracer gas tests. In addition, local point containment is achieved by local exhaust units that fit directly over the variously sized mauser drums. Operators have access to breathing air suits if desired. Fig. 9 shows a purpose-built containment unit used for

dispensing small quantities of highly active compounds. The extracted dust is collected in a specially designed bag house. The dust is remotely augered into drums in a self-contained recovery room equipped with air locks, respiratory air, and water decontamination showers. The bag house exhaust air is filtered through a bag-in/bag-out HEPA filter system.

OPERATIONAL COSTS

The operational costs vary greatly depending on the types and extent of utilities, as well as the technology incorporated. A sterile product facility is much more expensive to operate than a pilot plant manufacturing only solids. NCEs, which may present bioavailability and/or stability challenges, may require the use of newer, more expensive technologies. Operational costs can be minimized if the pilot plant is on the same site with a production facility where power-generation capability and support staff

Fig. 8 Weighing and dispensing room. Each mauser drum has special extraction units that fit directly over the variously sized drums.

functions, such as maintenance, calibration, engineering, housekeeping, security, validation, QA, microbiology, QC, shipping, receiving, and training, can be shared. If the facility is isolated, space requirements increase significantly and the support overhead increases the operational costs.

The building and operating costs can often be justified based on the direct costs of product development and clinical manufacture under contract. In addition, delays in clinical programs can cost the company millions of dollars in lost revenue. However, if building or operational costs cannot be justified, it may be more effective to outsource work to a CRO.^[24] This may be especially true for new or smaller companies.^[25–27]

In the past, CROs have been used by pharmaceutical companies to provide extra capacity in the later stages of development. More recently, CROs have expanded their role to include early stage development and specialized technologies.^[28]

Outsourcing to a CRO is not fail-safe. If it is to be a successful partnership, both companies must explicitly state the needs and expectations of each other. This should include considerations of confidentiality and ownership of intellectual property.^[29,30]

SUMMARY

The design and construction of pilot plant facilities must be well thought out in order to accomplish the strategic objectives desired. Flexibility in design is critical to allow product and process development, clinical supplies manufacturing, and process technology scale-up and evaluation to be carried out in an efficient, scientific manner. In today's business environment, the well-designed pilot plant is necessary to shorten the product development cycle, with the ultimate goal of getting new products and medicines to the market rapidly and efficiently.

ACKNOWLEDGMENTS

The second edition authors would like to sincerely acknowledge the work of the first edition authors—Robert M. Franz, Robert D. Copeland, Lawrence D. Lewis, and William C. Stagner. Most of the first edition's text is retained. The basic goal in revising the first edition chapter was to add current references. This was easily done with the excellent foundation and framework the first edition authors provided.

Next, the authors would like to acknowledge Alan F. Parr for reviewing the revised chapter.

Finally, the authors would like to acknowledge the administrative help of Cindy Rozier in preparing this revision.

INTRODUCTION

Several attributes of the pilot plant allow it to serve as a vital function in achieving the key strategic objectives of:

- Formulation and process development.
- Clinical supply manufacture.
- Technology evaluation, scale-up, and transfer.

These attributes include: 1) a current good manufacturing practices (cGMPs) environment; 2) a flexible highly trained staff; 3) equipment to support multiple dosage form development; and 4) equipment at multiple scales based on similar operating principles to those in production. These key attributes help define current trends in pilot plant operation. Most of the development and clinical manufacturing activities should be condensed and performed under cGMPs. The application of cGMPs early in the development process is mandated by the current regulatory environment, while at the same time market competition is demanding shorter development times. These aspects, and the often limited availability of drug substance, result in the necessity to obtain as much development information as possible from each and every batch manufactured in the pilot plant. Even batches targeted solely for clinical supplies often incorporate some aspect of experimental design, process optimization, or scale-up in an effort to maximize the information obtained during new product development.

In order to improve efficiencies within the pilot plant, many firms are abandoning the practice of having separate clinical supplies manufacturing staff and formulation process development staff in favor of a more flexible, responsive group capable of supporting product development from beginning to end. The staff must be trained in formulation development, process development, scale-up, technology transfer, cGMP compliance, and clinical supplies manufacturing. In order to maximize development

efficiency, it is crucial to incorporate clinical supplies manufacture, process development, scale-up, and technology transfer activities within the same departmental organization. To this end, a matrix-management approach is often utilized for project teams responsible for product development activities.

Although the pilot plant must simulate the manufacturing environment in which the new product will ultimately be produced, there are many differences in operation because of the specific objectives of the two types of facilities. The pilot plant facilitates product development activities, whereas the manufacturing plant routinely fabricates products for the marketplace. The pilot plant must be flexible in operation in order to accommodate the very nature of product development, which is often at odds with the routine required in a true manufacturing facility.

Recognizing and managing the difference in objectives between the pilot plant and production facility form the basis for success in pilot plant operation. This chapter highlights the unique operational aspects of the pilot plant environment.

VALIDATION

Most basic validation activities within the cGMP pilot plant are identical to those expected in practice in a manufacturing facility.^[1–5] A validation master plan should be developed that addresses the design specifications and qualification, installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ) of all major utility systems, process equipment, and computer control systems. Installation and commissioning data should be retained as part of an engineering documentation package. A workable change control system should be established. Process areas should meet or exceed current Food and Drug Administration (FDA) standards.

A fully validated pilot plant ensures compliance with cGMPs, but more importantly, guarantees data integrity during product development. Data generated during this period in the pilot plant are typically used to set product specifications and in-process controls, as well as process variable control limits. Validation of the utilities and equipment in the pilot plant ensures that the facility adequately simulates the manufacturing environment. This is especially true for automated equipment and equipment requiring validation of computer control systems.^[6] The information collected during product development in a validated facility provides the appropriate database for subsequent scale-up and technology transfer to the manufacturing site.

There are several areas within the pilot plant environment that routinely differ with respect to validation when compared to a production facility; these include manufacturing process validation, cleaning validation, and revalidation activities. Manufacturing processes within the pilot plant environment are often not repeated. A process may be implemented only once before a change in scale, equipment, or process variable is implemented. The usual manufacturing scenario of performing process validation on three or more identical sequential batches is often not relevant in the pilot plant environment. In order to ensure that each batch is acceptable, especially with respect to clinical use, it is important to collect sufficient in-process data to guarantee the quality of the batch.^[7] Data can be generated during the actual experimental development work showing that the process achieves what it purports to do, or extensive samples can be collected from each batch as manufactured. A combination of experimental data and batch manufacturing data may also serve to prove process integrity. Specifications should be set with respect to critical product characteristics, such as content uniformity and potency. The lack of a sufficient database and minimal experience with a process early in development often require that the specifications be set at the widest limits allowed by current regulatory guidelines, e.g., USP specifications. As experience with the product grows, and assuming the database supports it, specifications may become tighter as technology transfer proceeds.

Cleaning validation is different in the pilot plant environment than in manufacturing.^[8–10] Again, the lack of process repetition often creates the need to verify that equipment is clean before and/or after the manufacture of batches used in clinical studies on a per batch basis. This can be accomplished by swab testing critical product contact surfaces before and/or after equipment use to ensure that residual drug is absent or at an acceptably low level. Cleaning techniques for new chemical entities (NCEs) must be verified on materials of construction or

based on solubility before new compounds enter the pilot plant environment. This information, combined with a routine cleaning procedure, i.e., standard operating procedure (SOP), for a particular piece of equipment, may serve as an acceptable alternative to swabbing after every batch.

Finally, utility and equipment revalidation or validation review may be structured differently than techniques typically used in the manufacturing environment. Unlike the production facility, the pilot plant may not use every piece of equipment or system on a routine basis. In fact, some equipment may remain idle for significant periods of time. Revalidation may need to be scheduled based on hours in use rather than a program designed for periodic review. It should be pointed out that some equipment or systems might need more frequent revalidation activities because of lack of use. No matter what basis is chosen, it is imperative that a formal revalidation program be established in the pilot plant environment.

TRAINING

The development of a training program for pilot plant staff is complicated by the inherent diversity of operations and personnel. Unlike the production facility, which is highly specialized and subject to infrequent operation changes, the pilot plant must be prepared to make a variety of dosage forms in response to a wide range of product development programs. The diversity of pilot plant operations, equipment, and personnel requires a flexible entry, reinforcement, and remedial training program. An extensive tracking system and flexible scheduling system are also required. Most importantly, the training program must be developed to meet the changing priorities of the product development cycle while maintaining cGMP compliance in the manufacture of clinical supplies.

Training within the pilot plant can be broken down into four major areas:

1. Compliance with quality standards, such as cGMPs.
2. Safety and environmental responsibilities.
3. Compliance with SOPs.
4. Technical skills and knowledge.

The order in which these objectives are presented is referred to as the “top-down approach” to training. It has been used successfully in the pharmaceutical industry.^[11] A systematic approach to develop a cGMP training program should include formal training plans, written training manuals, effective training methods, assignment of responsibilities, written documentation and periodic

review, and written certification of instructors.^[12] A dynamic training process is extremely important. Initial training must be reinforced with current, up-to-date programs that address changes in job requirements, performance expectations, and technology.

Pilot Plant Staff

The staff operating the pilot plant is often diverse in educational background, work experience, and function. The multidisciplines can be divided into the broad categories of scientific groups, support groups, and contractors. The last two groups can be further subdivided into technical and nontechnical personnel. Regardless of the category, a basic training program should be defined for each. Access to specific areas of the pilot plant may be based on the level of training applied to a particular category of staff, e.g., sterile environment.

Training for the scientific group, which includes formulation and process development scientists, represents the majority of the training requirements. Personnel with diverse educational backgrounds may be challenged to operate in different areas of the pilot plant on a multitude of equipment in different dosage form areas. The mindset of the scientist is experimentation. The evaluation of formulations and processes is the focus of their work. It is extremely important that training be well defined to attain an adequate level of competency, and that all required training be completed prior to initiation of any pilot plant activity. This ensures the safety of personnel and equipment throughout the process and guarantees the manufacture of a quality product.

Cross-training scientific staff in the use of many types of pilot plant equipment is vital to carrying out efficient product development programs, but creates significant difficulties with respect to training. Reinforcement training becomes paramount in order to maintain the level of competency necessary to ensure proper operation of equipment and compliance with procedures. A well-trained individual who regularly performs an operation obtains the type of reinforcement necessary to successfully and correctly complete a task. For this reason, it may be necessary to devote highly trained scientific staff to operations in specific areas of the pilot plant, e.g., the sterile process areas. Other scientific staff with less expertise in a particular operational area can assist in development activities based on a lower level of basic training, but may be relegated to less technical operations compared to those with routine experience. It may sometimes be necessary to assign “experts” in a defined operational area of the pilot plant based on the

development activities required. On-the-job training with an experienced guide or “expert” is a simple and effective approach to entry and reinforcement training. Training provided by the equipment manufacturer can be useful in the completion of entry-level training and development of reinforcement training programs for the scientific and support staff.

The technical support groups must also be appropriately trained. They may represent equipment and facility engineering, maintenance, and calibration groups, as well as quality groups, i.e., QA/QC. Although their educational backgrounds may be very diverse, the focus of these groups is confined to pilot plant operation rather than the experimental techniques of the scientific staff. The greatest challenge with respect to training equipment engineering, maintenance, and calibration groups is to impart knowledge of how their responsibilities and actions in the pilot plant affect the ultimate quality of the products manufactured for clinical use. The quality groups typically have a good grasp on cGMPs and how their activities within the pilot plant can affect product quality. Training of quality groups is often very specific with respect to their responsibilities, but it is important that they also receive appropriate basic training in cGMPs.^[11]

The nontechnical support groups represent individuals responsible for cleaning and sanitation. Training requirements are usually limited to access specific areas of the pilot plant.

The importance of training temporary and contract labor should not be overlooked. The time period and frequency with which the contractor or temporary employee will operate within the facility and the required level of access should be used to define requirements.

Training Program

A pilot plant training program has several key aspects that may require a different approach compared to programs typically utilized in a production environment. These include identification of educational and instructional training programs and development of training manuals, individualized training syllabuses, and a documentation and tracking system.

Educational and instructional training programs should be defined for the facility based on the scope of operation of each functional area. For both educational and instructional training, manuals should be developed. The instructional training manuals can be divided into entry, reinforcement, and remedial training. Entry-level training is targeted for a new or prospective employee and should provide assurance that a certain skill level has been attained.

Reinforcement-level training is intended for an employee who has already been trained in a certain area. This training is intended to reinforce skills already acquired and to prevent performance problems. Remedial training is intended to correct identified skill deficiencies. The training required for equipment may range from reading the SOP and completing an evaluation form, e.g., test, for simple equipment to more extensive supervised and documented practical experience with a qualified trainer.

Pilot plant educational courses are usually tailored to a general audience since they impact all personnel. Instructional courses, however, may be very technical and assume a certain level of competency. In all cases, the evaluations developed as part of the training manual should effectively assess the student's level of competency. Any deficiencies identified in the assessment should be immediately corrected with additional training.

New technologies, frequently encountered during the development process, affect pilot plant training programs. New technologies pose a special problem because training must be conducted by a qualified individual. Some new technologies can be studied at the equipment supplier's facility and subsequent initial training can occur in the pilot plant with a representative of the equipment manufacturer as trainer. For technologies invented in the development group, it is recommended that the inventor become the initial trainer.

The diversity of pilot plant operations to be performed and the variety of personnel involved require an individualized training syllabus for each employee. The "top-down" approach mentioned previously works well in this regard. The focus is again to complete the higher education courses before proceeding to the instructional or area-specific procedures. Access to and operation within the pilot plant areas can be controlled by successful completion of basic requirements defined for each functional area. A simple way to identify and document each individual's training requirements is a checklist of courses and procedural training required based on the pilot plant area and function within the area. The employee reviews the checklist with management and identifies the training required to work on a particular project within the pilot plant. The result is a documented individualized training syllabus. Once defined, the syllabus can be used to train personnel to meet the resource needs for the project.

All training must be documented and a tracking system established by using the individualized syllabus to identify initial and reinforcement training requirements. The syllabus can also be used for entry into a database or one of the commercially available computer tracking systems.

A master schedule of courses should be developed for distribution to the pilot plant staff. Scheduling of courses

can be very resource demanding, depending on the types of courses. Resources can be optimized with the help of videos, computer-based training (CBT), and well-designed self-study courses. However, the benefits of group "on-the-job" training are important in reinforcing the learning gained by self-study courses.^[13]

Training Media

Self-study programs have been used to successfully meet the challenge of training a diverse pilot plant staff. The computer industry has made significant strides in learning retention with the aid of visualization technologies based on increased information storage capabilities on compact discs.^[14] The techniques include interactive CBTs and interactive audio and video compact discs (CD-I).^[15] The former is enhanced by interactive courseware, which stimulates interest and documents completion of the course work. Distribution of multimedia over local and wide area networks (LANS and WANS) offers additional flexibility in that the operator can access the training program from work and operational areas. The advantages of these types of technology to pilot plant staff include:

- Immediate availability of material for entry or reinforcement training from various work locations.
- Immediate retrieval of specified information.
- Visual representation of procedures and operations.
- Consistency of instruction.
- Personalized learning rate.
- Practice by performing simulated operations.
- A more conducive environment for cross-training.

Although some of these advantages are limited by current technologies, more sophisticated training media based on enhanced visualization systems will be available in the future.

ENGINEERING, MAINTENANCE, AND CALIBRATION SUPPORT

As pilot plant facilities and operations become more complex and technically diverse, the need for support groups, such as engineering, maintenance, and calibration, becomes critical to perform planned activities in a cGMP-compliant manner.

Engineering

Engineering and architectural support is obviously required during the design, construction, commissioning,

and validation of the pilot plant facility. However, some larger facilities may require dedicated engineering support staff for the coordination, scheduling, and direction of ongoing operations. The primary objective of the engineering staff is to provide timely support and direction in facility and equipment requirements necessary to ensure the efficient implementation of drug development projects. Support provided by the engineering staff may include:

- Equipment acquisition, installation, and repair.
- Engineering documentation and control for new systems and equipment.
- Management of the facility to ensure that critical systems, e.g., environmental controls, utilities, etc., are operational for compliance with cGMPs.
- Coordinating and scheduling equipment set-up and related activities for development projects.
- Ensuring a controlled inventory of critical spare parts, e.g., tablet tooling.
- Budgeting for equipment, technology upgrades, and operating supplies.
- Directing housekeeping activities.

Engineering support staff also play a pivotal role in pilot plant operation by contributing to the selection and evaluation of new process and material-handling equipment, recommending containment techniques to minimize exposure to potent drugs, and providing support for new technologies which may be critical in the development of an NCE. Equipment evaluation, procurement, installation, and qualification can be enhanced by the formation of project teams, which include engineering and scientific staff, as well as members from purchasing, validation, calibration, maintenance, safety, environmental, quality assurance (QA), and other necessary functions. A written procedure outlining the roles and responsibilities of members of the team can be critical to the successful implementation of a new facility and process technologies necessary for product development.

For large facilities, internally developed or commercially available computer software has been found useful for the engineering support staff in scheduling process equipment and space for development, maintenance, calibration, and validation activities.^a

Maintenance

A maintenance program is necessary within the pilot plant to meet the requirements of cGMPs and to ensure data

integrity and equipment reliability during the development process. The maintenance program must be documented and written procedures established. All maintenance activities on critical systems and equipment must be documented, approved, and archived for retrieval during FDA inspections. Changes not considered routine must be documented and approved through an established control procedure. It is important to document critical changes to computer systems or code necessary for maintenance activities.

Although the basis for a pilot plant maintenance program is similar to that of a production facility, there are several differences worth mentioning. The pilot plant maintenance program may be more diverse with respect to systems and equipment because of the nature of product development. Furthermore, equipment utilization within the pilot plant may be less routine than in the manufacturing environment, requiring a different approach to preventative maintenance. A preventative maintenance program based on hours of utilization may be warranted for some equipment in the pilot plant rather than the typical scheduled approach, e.g., annual, semiannual, etc. Another approach is to routinely review the utilization of equipment in the pilot plant and reestablish the preventative maintenance program based on historical data. This requires close interaction between engineering support and maintenance staff. The results are significant improvements in resource utilization and efficiency during preventative maintenance activities.

It is critical that the maintenance staff operating within the pilot plant be responsive, well trained, and has expert knowledge of equipment and systems in the facility. Staff members should be keenly aware of how changes to critical systems and equipment can affect product quality. An effective written procedure is recommended for communicating critical variances identified during routine and nonroutine maintenance activities. Changes and variances must be communicated in a rapid manner to the engineering support staff and ultimately to the scientists in order to ensure the integrity of ongoing development work. Quality staff should be rapidly notified if clinical batches are affected in any way so that appropriate actions can be implemented.

A computer-based system for facility management, control, and data archiving is useful for identifying critical systems that may require maintenance, as well as trending alarms and environmental data for routine review.^{[16]b} Vibration analysis systems have been found useful in predicting maintenance and repair needs of motors and other systems.^[17]

^b<http://www.wonderware.com/home.htm> (accessed November 2001).

Calibration

Routine calibration of critical instruments on systems and equipment is required for compliance with cGMPs, as well as for maintaining the integrity of data generated during the development process. The pilot plant environment is often more complex with respect to instrumentation than that found in manufacturing. A preponderance of data is often collected through extensive instrumentation during product and process development in order to determine critical and noncritical process variables and control levels. Once this information has been collected and analyzed in the pilot plant, only process variables deemed critical and their related instrumentation may be transferred to the manufacturing environment. For these reasons, pilot plant calibration staff must be well trained and have expertise in a wide range of instrument technologies. As with maintenance personnel, they must be fully aware of the effect of calibration-related activities on product quality, and variances should be relayed to appropriate engineering, scientific, and quality staff via written procedures. Because of the extensive instrumentation on equipment and systems, it is important that engineering, calibration, maintenance, and scientific staff determine those that are critical to product quality. Critical instruments should be routinely calibrated and identified as such to the user. Noncritical instruments may be used to collect additional data. They are often calibrated separately as part of the routine preventative maintenance program.

MATERIAL CONTROL, INVENTORY, AND DISPENSING

Material flow and control in the pilot plant require flexibility, precision, and broad scope. There are major differences between production and pilot plant facilities with regard to these activities. For example, long-range planning for the manufacture of development and clinical batches is often limited, inventory is highly varied and often not used repetitively as a result of the experimental nature of development activities, and material use and quality status must be considered as dispensing is planned. Conventional paper tracking systems can be used and are highly effective in many manufacturing and pilot facilities, but it is desirable to implement a more flexible and efficient computerized system in the development-oriented environment of the pilot plant. The system should distinguish between various function-based user groups. Membership in a particular group determines what system capabilities are available to the user. The detailed

description that follows addresses how experimental and clinical supply requirements can be controlled and separated within the pilot plant, allowing maximum flexibility of activities.

Inventory

Inventory can be maintained in a validated computer-based inventory–ordering–dispensing system. Inventory may consist of stock articles, which are kept on hand for general use, and specialty articles, which are ordered for a particular purpose. The former should be automatically tested for approval, whereas the latter can be received into inventory as either clinical or experimental material. Clinical materials must be fully tested and formally approved prior to use. Experimental items are available for nonclinical work only. This approach allows tracking of all lots received, while minimizing resource requirements in the QA and quality control (QC) areas.

Articles must be identified in the inventory database with a unique code before they can be received into the pilot plant.^[18] Upon receipt, the materials should be checked, verified, and labeled with inventory and quarantine labels. A receipt report is electronically received by the QA group, which initiates appropriate sampling. The sampled material, which to this point is kept in a secure holding area, is moved to a warehouse upon release by QA.^[19] Any change of location is recorded in the computer system.

Quantity, status, and location of inventory should be ascertained using a statistically based method, which can separate the inventory according to the frequency of usage. Articles with high activity are sampled at a higher rate. Inventory accuracy, in terms of quantity, must be maintained within predetermined levels, for example, between 95% and 105% of the actual level, or an investigation will be required to identify the cause of the discrepancy.^[20] This approach differs from the cycle count methodology typically employed in a manufacturing operation.^[21]

Inventory quantity, status, and location should be tracked at the container level. The system should allow users to review inventories on-line, or in printed form, via a series of predefined queries and reports or via flexible queries, which may be generated on an ad hoc basis. Access to the system should be available via any number of remote terminals.

Orders

All orders must be placed through the computer system. A batch or general order can be placed for any article defined

in the inventory system directly from a desktop computer. Placement of a batch order automatically generates a batch number. General orders are placed for all articles not used in a batch formulation.

The ordering mechanism should differentiate between order types (experimental vs. clinical), which will allow the system to check the intended use against the material status. Should the material status not be suitable for the intended use of the requested lot, e.g., quarantined or experimental material has been ordered for clinical use, the user should be alerted immediately to resolve the issue. A hold can be placed on the order, pending attainment of the proper material status. During this time, dispensing of the article in question is blocked. The ordering procedure should be flexible to the point that an individual placing an order may select a dispensing weight variance, e.g., $\pm 1\%$, identify a specific lot and container, or allow the system to pick the lot and container automatically based on first in, first out (FIFO) criteria. The order may also be employed to describe use, reference a notebook number, or conduct other activities.

The dispensing of designated materials, typically drug substances, should require specific authorization before the order can be completed. Materials that require this degree of control are identified during the definition stage, prior to formal receipt into the facility. An order submitted for dispensing can be printed in the dispensing area for scheduling by dispensing personnel. Receipt of the order, projected dispensing date, and completion for dispensing can be confirmed and communicated to the requester via electronic mail.

Labeling

The system must provide the ability to print various inventory, sample, and pre- and post-dispensing labels. All labels should include a bar code and printed text with the pertinent batch and/or lot information. Labels must comply with GMP–GLP (good laboratory practices) requirements to meet the needs of both laboratories and clinical manufacturing. Labels should be available in multiple sizes to accommodate laboratory sample containers as well as production drums.

Future Systems

The electronic inventory, ordering, and dispensing system is the first step in creating a computer-based system to support the areas requiring GMP documentation, and/or manually intensive operations, which provide a

disproportionately small return on the effort invested. Future improvements to the system include:

1. An electronic interface between the user, the inventory system, QA, and purchasing to support a paperless purchase order.
2. Electronic logbooks.
3. Electronic batch records.

Implementation will improve efficiency as well as quality compliance by consistent application of regulatory guidelines. Ancillary benefits include the ability to retrieve documentation quickly for an FDA inspection and the development of accessible product histories, which can be electronically passed to operations as products move from development to commercial sites.

PROCESS AND MANUFACTURING ACTIVITIES

Pilot plant processes and manufacturing activities include formulation and process development studies, clinical supply manufacture, and technology evaluation, scale-up, and transfer. Packaging for stability and clinical studies may also occur in the pilot plant, but these activities are often performed in separate, well-defined facilities. It is beyond the scope of this article to discuss all of these areas in detail. Since pilot plant construction is often driven by the strategic necessities defined earlier, only these areas are addressed.

Formulation and Process Development

Scientific staff must be able to access the pilot plant and operate in an experimental mode using procedures and processes without compromising the cGMP integrity of the facility.^[22] Procedures should be flexible enough to allow development batches to be manufactured in a fashion considered efficient by the development scientist. As previously discussed, it is important to have a detailed material control, inventory, and dispensing system in place to address differences in materials for experimental and clinical manufacturing. In-process and finished products should be labeled and recognizable with respect to experimental vs. clinical materials. For some early development work or evaluation of new technologies, equipment may be utilized before being fully validated. Research notebooks, rather than formalized batch records, are a necessity in the development environment. Quality group involvement with the manufacture of experimental batches may be limited. Typically, procedures that address

the operational aspects of the facility are equivalent no matter what the manufacturing activity. For example, equipment and room logs, cleaning procedures, training in equipment operation for safety purposes, and environmental monitoring programs should be transparent with respect to manufacturing activities.

Clinical Supplies

A key activity in a well-designed pilot plant is the manufacture of clinical supplies. A pilot plant should be flexible in design in order to accommodate a wide range of dosage forms. Flexibility provides the following advantages, which are directly applicable to clinical supply and “comparator” (positive clinical control) manufacture:

1. The optimum dosage form is chosen for development based on physical, chemical, or biological attributes of a new compound.
2. Different dosage forms can be developed in response to different patient demographics.
3. Comparator dosage forms can be developed which are different than forms routinely manufactured.

Efficient clinical supply manufacturing requires a wide range of equipment sizes, preferably of identical design, to handle requirements based on bulk drug supply. Clinical supply needs can quickly move from a few hundred dosage units in Phase I–II studies to millions of dosage units for Phase III–IV studies. The ability to rapidly scale processes is directly linked to the availability of similar, if not identical, equipment at the large scale. As clinical supply needs continue to grow, production of a few large batches compared to several smaller batches results in a substantial savings in time and resources for processing, testing, and documentation. The generic regulatory requirement that biobatches of solid, oral dosage forms one-tenth of the planned commercial batch size, or at least a minimum of 100,000 dosage units, highlights the advantage of producing large batches of clinical supplies in the pilot plant.

The quickest route of entry into a clinical trial is often through the use of a sterile parenteral dosage form. An ampule may be desirable early in development because only one material has to be considered for product compatibility, allowing rapid development and entry into clinical studies. The sterile process areas within a pilot plant should be operated with the same degree of control as those found in a routine manufacturing facility. Because of the unique environment, training required, and specialized operating procedures, sterile process areas within the pilot plant should strictly adhere to defined regulatory

requirements and be operated under cGMPs.^[23] The microbiological integrity of the area must be maintained by regular cleaning and sanitation. The sanitation program may revolve around the utilization of the area. Periods of heavy use may require more frequent sanitation. Ultimately, the environmental monitoring program determines the frequency required.

Because the scientific staff may utilize the sterile process area on an infrequent basis, training is critical.^[24] Staff expecting to work in the area should be thoroughly trained and participate in regularly scheduled bacteria–growth–media fills. Since batch sizes may be smaller than those typically found in production, the number of units filled during bacteria–growth–media simulations may be based on the actual scale and process time of the product manufactured in the pilot plant environment. It is recommended that at least 3000 units be filled to meet current regulatory guidelines if the scale of equipment warrants.^[23]

A range of process equipment should be available for the manufacture of sterile clinical supplies:

1. Glass and stopper washing and siliconization equipment.
2. Dry heat and steam sterilizers.
3. Ampule and vial fillers.
4. Freeze dryers.
5. Capping equipment.

The process equipment should cover a wide range of sizes, units, volumes, and operating conditions, e.g., speeds, for maximum flexibility in relationship to batch size and sterile dosage form requirements. Examples of pilot plant equipment utilized for the manufacture of sterile products are shown in Fig. 1.

As in a routine production facility, programs for environmental monitoring of viable and nonviable particulates, bioburden, and pyrogen loads of incoming materials should be established. Prewashed and sterilized components may be useful in improving operating efficiency.

The ability to manufacture a wide range of solid and nonsterile liquid dosage forms within the pilot plant is required for efficient clinical supply development. Areas within the pilot plant dedicated to nonsterile manufacturing should be of flexible design. Operation in these areas should meet the same standards of cGMP required in a routine manufacturing facility. Flexibility in equipment size is required to meet demands based on drug availability. Since many clinical supplies are double-blinded with the help of encapsulation technology, equipment should be capable of filling and overfilling

Fig. 1 Sterile dosage form processing equipment useful for clinical supply manufacture in the pilot plant. (a) Vial and ampule washer (Metromatic, Oyster Bay, NY). (b) Steam sterilizer (Amsco Finn-Aqua, Apex, NC). (c) Vial filler (TL Systems Corp., Minneapolis). (d) Lyophilizer (Edwards High Vacuum International, Tonawanda, NY). (e) Vial capper (The West Co., Phoenixville, PA).

powders, granules, beads, and tablets into hard gelatin capsules. Fig. 2 shows typical encapsulation equipment for the manufacture of clinical supplies.

Aerosol and semisolid dosage forms may be required in some clinical trials. Aerosol manufacturing needs semiautomatic and automatic equipment (Fig. 3) with the capability to produce from 100 to 10,000 units in order to meet clinical supply demands.

All of the above mentioned dosage forms may be utilized in clinical trials as the developed product or as a clinical comparator. Clinical “comparators” (positive clinical controls) are an outgrowth of the regulatory environment in which Phase III clinical studies must include the comparison of the generally recognized therapeutic treatment with the NCE being developed and a placebo. To avoid bias in the clinical program, the

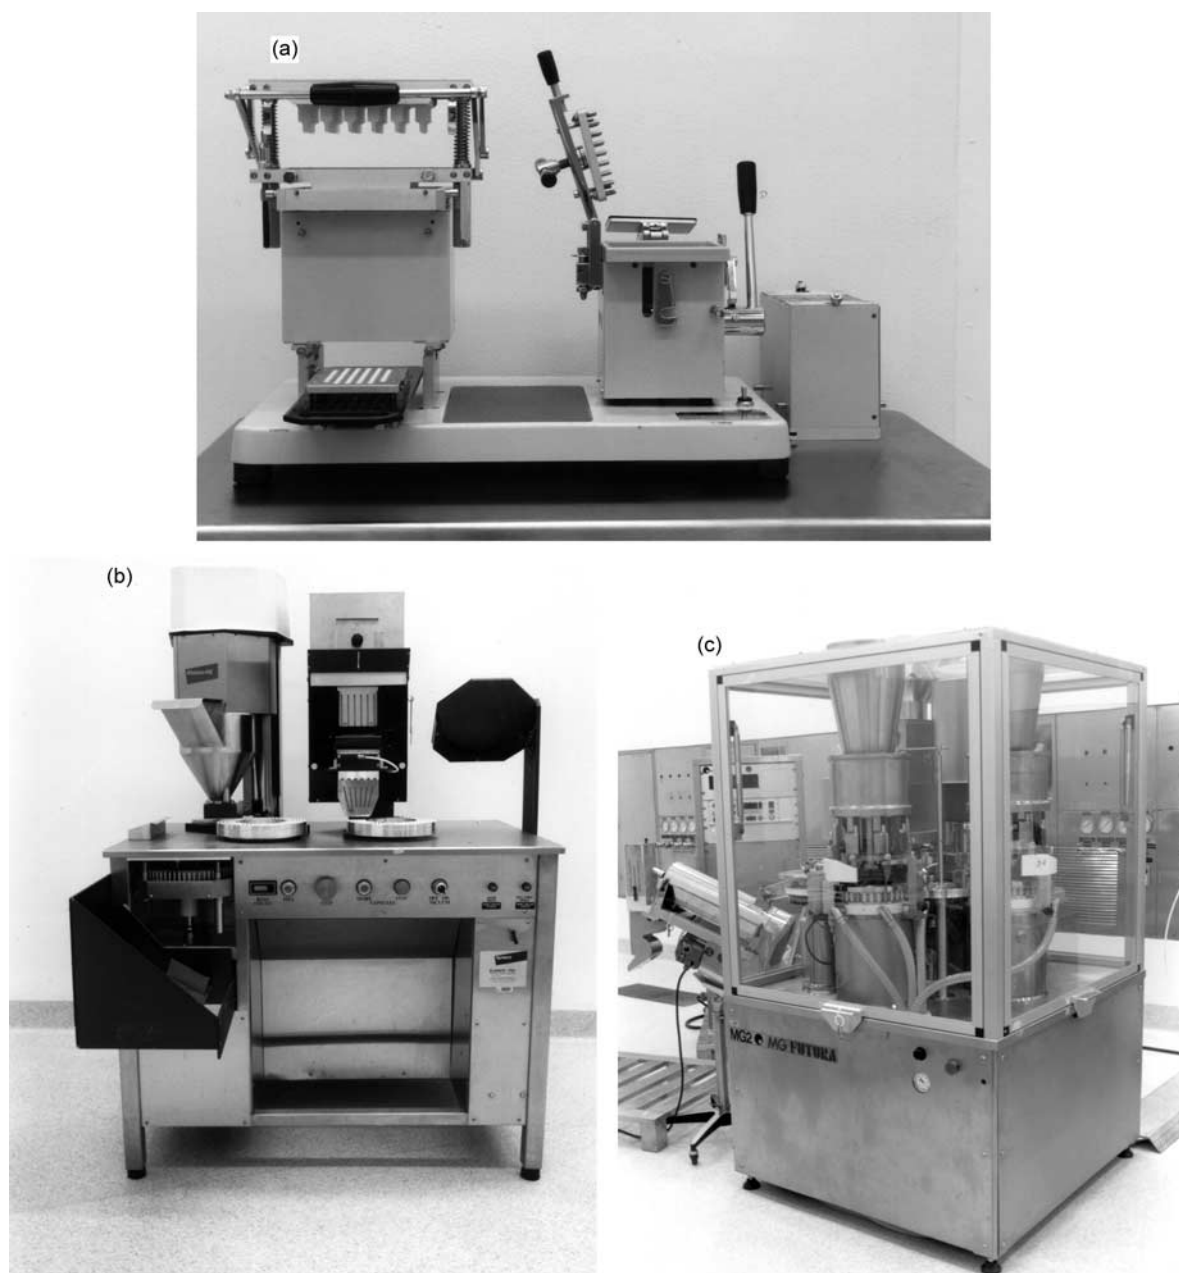

Fig. 2 Encapsulation equipment useful for clinical supply manufacture in the pilot plant. (a) Manual encapsulation equipment (Dott. Bonapace & C., Milano, Italy). (b) Semiautomated encapsulation equipment (Elanco Qualicaps, Indianapolis). (c) Automated encapsulation equipment (MG America, Inc., Fairfield, NJ).

comparator and placebo products are blinded, that is, manufactured in such a way that they are virtually indistinguishable from each other. For products that differ in dosage form, a double-dummy design is often employed. For example, if an NCE is being developed as a tablet and the desired comparator is marketed as a metered-dose inhaler (MDI), identical placebos of each

product would be produced. The patient in the clinic would receive an active MDI along with placebo tablets or vice versa. The blinding of comparator agents often mimics the development program for an NCE, but with greatly reduced timing. The blinding process typically requires limited preformulation studies, formulation studies, process development and optimization, scale-up and

Fig. 3 Aerosol filling equipment useful for clinical supply manufacture in the pilot plant. (a) Manual filling equipment. (b) Automated rotary filling equipment (both D. H. Industries Limited, Barking Essex, UK).

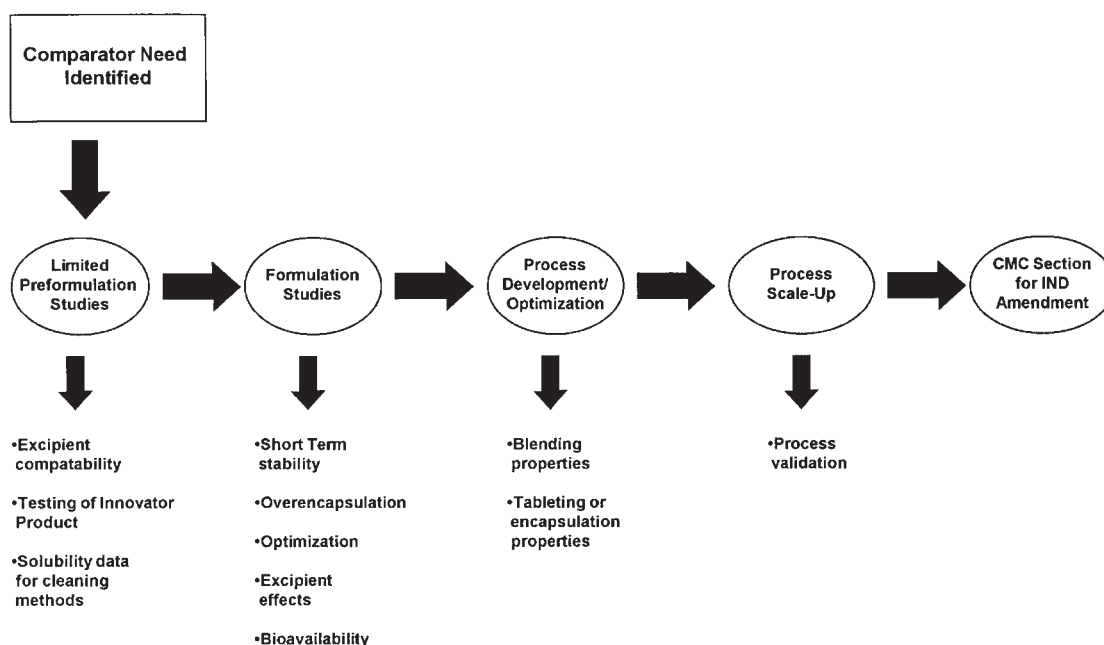

Fig. 4 Typical activities in the development of blinded clinical comparators.

regulatory documentation. Depending on the process, in vivo bioequivalence studies may also be required to ensure that blinding does not alter drug availability. Fig. 4 gives the details of the activities involved with the development of blinded clinical comparators. Blinding techniques for common dosage forms are shown in Table 1.

A matrix team approach has been utilized successfully by the authors to optimize the interfacing between development groups, support groups, and customers (medical or marketing groups) when preparing to manufacture new clinical supplies or comparators. This ensures that the finished products meet the customer's needs. Fig. 5 is a process map showing key matrix groups and activities typically involved with supplying clinical dosage forms. The breadth and scope of clinical supplies manufacturing, packaging, and shipping activities can become remarkably complex as illustrated by the following detailed description of a single block activity taken from Fig. 5 (preparation for manufacturing and packaging):

- Finalization of dosage formulas.
- Development, validation, and transfer of analytical methods.
- Final product specifications.
- Schedule of manufacturing.
- Secrecy agreements and statement of work and service contracts for contractors.
- In-process tests and specifications.
- Cleaning of manufacturing facility.

- Cleaning of equipment.
- Swabbing of equipment for residuals.
- Testing of equipment by microbiological means.
- Testing of facility by microbiological means.
- Sampling requirements.
- Swab results.
- GMP validation audit (contractor).
- Product–item code identification.
- Raw materials order.
- Certificates of analysis (COAs) for raw materials.
- Raw materials receiving and sampling.
- Testing of raw materials and recommendation for release.
- Raw materials release.
- Packaging materials order.
- COAs for packaging components.
- Release of packaging components.

Once a specific clinical product or comparator is developed, it may become more efficient and cost effective to manufacture and stock bulk supplies from the pilot plant when it is known that they will be routinely used in future clinical studies.

Technology Evaluation, Scale-Up, and Transfers

The pilot plant and its staff play a critical role in technology evaluation, scale-up, and transfer activities of new pro-

Table 1 Blinding Techniques for Common Clinical Dosage Forms Manufactured in the Pilot Plant

Techniques	Purpose
Solids^a	
Overencapsulation of intact tablet or capsule and filler	Stability testing and comparative dissolution
Film coating to obscure logos and proprietary color	Stability testing and comparative dissolution
Milling of dosage form and recompression on standard tooling	Stability testing and bioequivalency test
Milling of dosage form and encapsulation of powder	Stability testing and bioequivalency test
Encapsulation of tablet granulation	Stability testing and comparative dissolution
Sugar coating of tablets to obscure engravings	Stability testing and comparative dissolution
Liquids^b	
Repackage product and produce matching placebo	Stability testing
Obliterate all product labeling and packaging matching placebo in identical container dosage system	Stability testing of placebo
Metered-Dose Inhalers^c	
Obliterate all product labeling and produce matching placebo utilizing identical valve and canister, (utilize active product actuators for active and placebo products)	Stability testing of placebo only
Powder (for reconstitution)^d	
Obliterate all labeling and product packaging for a matching placebo powder	Stability testing for placebo only
Repackage product into standard packaging and produce packaging for a matching placebo powder	Stability testing for active placebo

^a For critical studies, bioequivalency testing should be considered in all cases. All techniques typically require the development of a matching placebo dosage form. Overencapsulation of a bead-filled capsule may necessitate a bead-filled placebo to match the rattling sound of the active product.

^b Color, clarity, viscosity, smell, taste, and identical packaging are critical blinding parameters.

^c Canister pressure, fill weight, actuation sound, and taste are critical blinding parameters.

^d Powder color, texture, particle size, fill weight, smell, ease of reconstitution, reconstitution volume, viscosity, taste, color stability after reconstitution, and physical stability of suspension are critical blinding parameters.

ducts. These activities begin early in the development cycle and include technical aspects of process development and scale-up, organization and responsibilities of technology-transfer teams, documentation of the transfer process, and often preparation for an FDA pre-approval inspection (PAI). A properly designed and operated pilot plant can enhance the collection of scientific data necessary to support internal transfer activities, as well as regulatory submissions and FDA PAIs.^[25]

Following are four key technical aspects that must be addressed during scale-up in the pilot plant:

1. Identification and control of critical component and formulation variables early in development.
2. Pilot plant equipment that simulates as closely as possible equipment used at the manufacturing site.
3. Identification of critical process parameters and operating ranges with pilot plant equipment through the use of engineering and regression models, i.e., statistically designed experiments.

4. Collection of product and process data to adequately characterize each unit operation.

The facility design plays a critical role in addressing each of these technical aspects. However, scientific and pilot plant staff involved in manufacturing operations within the pilot facility also play a key role in ensuring the smooth and timely transfer of process technology to the manufacturing site.

In the past, the transfer of formulation and manufacturing technology was sometimes discretely passed from development staff to manufacturing staff with little interaction or foresight. Nowadays, however, it is commonly recognized that interaction of these groups at an early development stage is critical in obtaining an efficient and successful transfer. Scientific and pilot plant staff play a key role in demonstrating new product manufacturing techniques to production personnel in the pilot plant environment. A team-oriented approach to the manufacture of pilot or large-scale batches in the pilot plant will

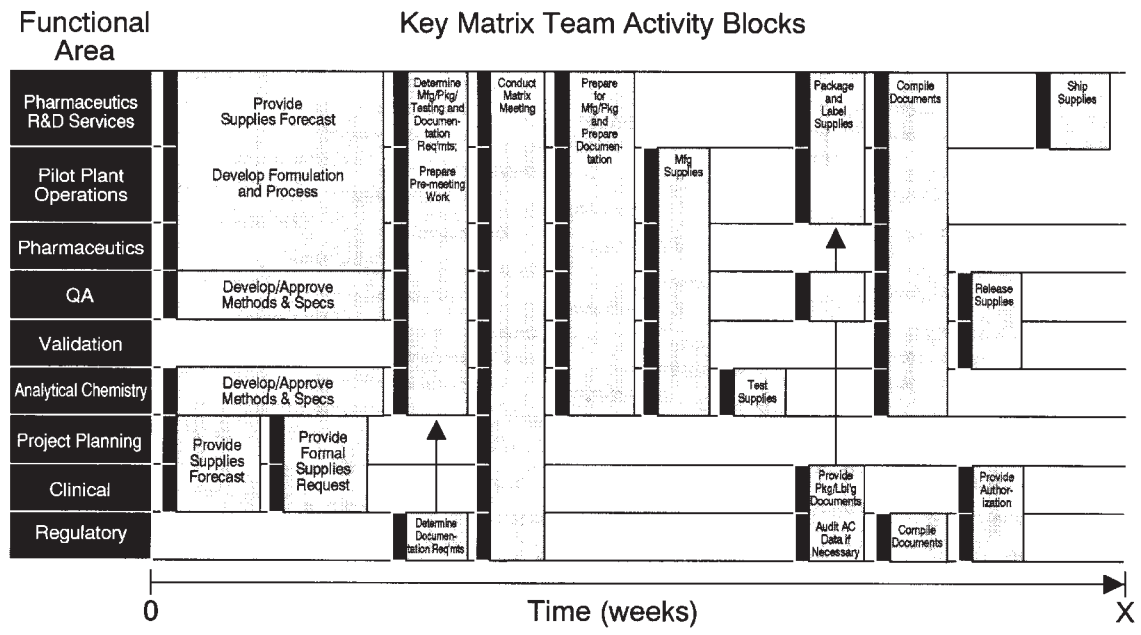

Fig. 5 Process map depicting key functional areas and matrix-related activities involved with supplying clinical dosage forms from the pilot plant.

allow key production site personnel to view and comment on the process and make specific recommendations for improvement based on knowledge of the manufacturing site. An example of the matrix team approach to the

transfer of manufacturing technology, key development, and production milestones, and the activities related to these milestones, is presented in Fig. 6. Interactions between pilot plant staff that begin during product

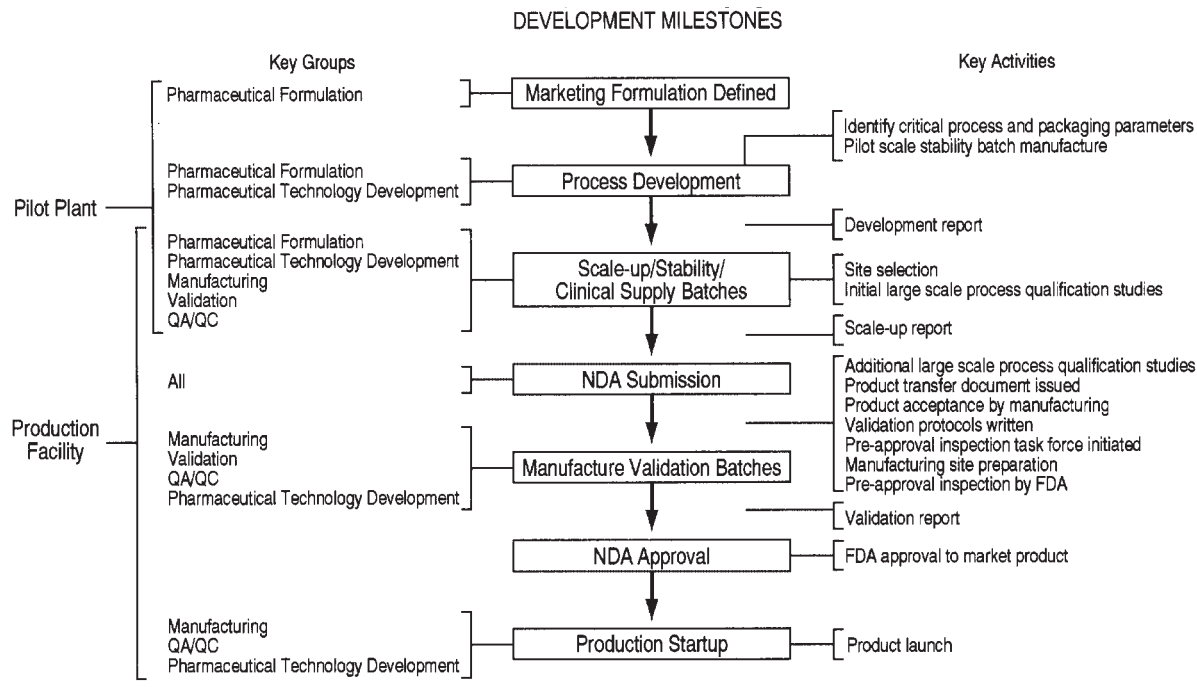

Fig. 6 The relationship of key groups, activities, and development milestones typically experienced during the transfer of formulation and process technology from the pilot plant to the production facility.

development and carry through production start-up ensure a smooth transition of the product to the marketplace.^[26]

Precise documentation of manufacturing trials at both the pilot plant and the production facility, with comparison of the results, assists in the development of a rationale relating biobatches and stability batches manufactured at the pilot scale to full scale product manufactured at the production site. Establishing the link between pilot and production scale batches is often critical in obtaining a successful FDA PAI.

QA–QC

As the size and complexity of the pilot plant increases, it may become necessary to have dedicated staff in the QC and QA areas to ensure compliance with cGMP and other regulatory requirements.

QA

The FDA promulgated that when the drug development process reaches the stage where product is manufactured for human use, compliance with cGMP is required.^[27] The facility should be validated with respect to utilities, equipment, and procedures and meet necessary regulatory requirements. Activities of the pilot plant QA scientist may differ from those performed at the production facility. The QA scientist should establish the procedural systems required to operate the pilot plant in a cGMP-compliant manner during the drug development process, especially with respect to clinical supply manufacturing. The QA scientist responsible for pilot plant activities should have a firm grasp on the breadth and scope of new product development activities and how regulatory requirements should be applied in the development atmosphere of the pilot plant. It is recommended that QA personnel be included as part of the team responsible for new product development in order to maintain an awareness of specific project activities in the pilot plant and provide expertise when necessary. Other QA activities similar to those in the production environment include documentation control of the production process and QC laboratory, raw material control, in-process material control, addressing deviations, overseeing production cleaning and processing, assessing of product quality, and establishing training programs for the pilot plant.^[28] It is particularly important for smooth operation of the pilot plant that systems, procedures, and communication links be established in all these areas and that pilot plant staff be fully aware of and trained in each.

QC

The QC function responsible for activities in the pilot plant may be structured somewhat differently than that found in a production operation. Release testing of finished products and materials may be undertaken by the analytical chemistry group responsible for the development of methods for an NCE. Release testing of materials and products for clinical studies in which methods have been formally developed may be undertaken by a separate QC group. For larger, more complex pilot plants, it becomes necessary to have a pilot plant QC function dedicated to the facility and responsible for physical, chemical, and microbiological testing of finished clinical products, components, and raw materials; physical, chemical and microbiological environmental sampling, testing, and trending within the pilot plant, e.g., water, compressed gases, air; and testing for validation and revalidation programs. It is also advantageous to have the QC team perform in-process testing during development, scale-up, and technology transfer activities. The QC personnel may become involved with project teams responsible for new product development and lend their expertise when required.

SUMMARY

The pilot plant is designed with basic strategic objectives in mind. As the facility becomes larger and more complex, organizational support is required from a number of technical disciplines. Although many activities are similar to those required in a production facility, it is imperative to recognize that basic differences exist between the research and development (R&D) environment and the manufacturing environment. Organization of personnel and definition of activities revolve around the development of new compounds and products rather than routine manufacturing. Successful operation of the pilot plant requires that these differences be taken into account, structured, and managed toward efficient new product development while meeting the rigorous scientific and regulatory standards required for the pharmaceutical industry.

ACKNOWLEDGMENTS

The second edition authors would like to sincerely acknowledge the work of the first edition authors—Leonard A. Amico, Ralph B. Caricofe, James D. English, Gary W. Goodson, Lawrence D. Lewis, and Robert

M. Franz—and those who provided critical reviews and helpful input for the first edition of this chapter—Bob Copeland, Bill Stagner, Phil Keicher, Ray Starrett, Mike Jozwiakowski, Linda Parks, Ken Korndoerfer, June Mullaney, Dave Moyer, and Anh Nguyen. Most of the first edition's text is retained. The basic goal in revising the first edition chapter was to add current references. This was easily done with the excellent foundation and framework the first edition authors provided.

Next, the authors would like to acknowledge Alan F. Parr for reviewing the revised chapter.

Finally, the authors would like to acknowledge the administrative help of Cindy Rozier in preparing this revision.

HISTORY OF PLANTS AS DRUGS

Phytomedicine, the use of plants or plant parts to evoke a therapeutic cure or to treat an ailment, has been part of humankind's attempt to free itself of disease for several thousand years. Some references suggest that Neanderthals may have been one of the first phytomedicinal practitioners. Archeologists exhuming relics from lake beds in the Middle East have found evidence suggesting that early human's carried plant parts for more than just food or clothing. Some of the earliest writings found in Babylonian clay tablets from 3000 B.C. are about plants used for ceremonies, magic, and medicine. During the next thousand years, parallel cultures in China, India, and Egypt developed written records of medicinal herbs. Among other early historical documentation, the ancient Middle Easterners appear to have been the one of the first to rigorously document the use of plants for various diseases, compiling the first known pharmacopoeia, entitled the *Materia Medica*. The Greek historian Herodotus recounts how the Egyptians worshiped certain plants, believing that the some plants held the secret to a healthy life and longevity. Not to be outdone by the Egyptian peoples, the Greeks incorporated various plants and flowers into various aspects of Greek mythology. One of the largest compilations, dating approximately 600 B.C., is credited to a series of Chinese emperors and provides detailed instructions about the use, benefits, and preparation of herbs.

Scholars throughout the centuries have made valiant attempts to demystify herbs; however, people continued to hold deep beliefs about the significance of plants. The Doctrine of Signatures, dating from the first century A.D., suggests that some aspect of the plant's appearance provided clues to its medicinal properties. This belief remained popular for 15 centuries and is noted in many Asian and Western cultures, including that of the Native Americans.

In the beginning, these primitive medicinals were used primarily in their natural form and incorporated into compresses and poultices. Much of the knowledge obtained from these first pharmaceuticals was put to use

by Native Americans and early American colonists. Not surprisingly, plants were manipulated into somewhat more complex formulations known as decoctions and infusions, the fundamental herbal preparations resembling modern-day teas. Typically, these botanical remedies were given to folks suffering from illness without regard to prior investigation. Formulas for various ailments were passed down from household to household much like recipes in a cookbook.

As science emerged after the 17th century, plants were classified and demystified. New technical skills permitted analysis of the plant's components so that standardized tinctures and extract could be prepared. Extraction of the relevant chemicals from these plants became popular around the turn of the 19th century. Active principal components such as opium and digitalis were isolated and applied therapeutically, although still lacking much in the way of formal prior investigation. As science advanced, medicines were synthesized and herbalism declined. Newly developed principles of organic chemistry made it possible to replicate plant-produced chemicals, paving the way for creative manipulation of these molecular entities, leading to the synthesis of new compounds that preserved the beneficial properties of the natural chemical, but minimized its toxic effects. The conception of local anesthetic agents from the naturally occurring alkaloid cocaine and the creation of the aspirin from natural salicylic acid in willow bark are important hallmarks that characterize the beginning of the era of "allopathic" medicines.

Many medicines that we use today were isolated from plant sources (Table 1). Examination of today's allopathic medications reveals that approximately 25–33% of currently available modern medicines in the United States have their origin in plants, animal, or mineral systems. These include aspirin, digoxin, quinine, colchicine, and vinca alkaloids, to name a few.

The focus on synthesized and biotechnolgy medicines has continued. However, in the latter part of the 20th century, there has been an intense renewed interest in

Table 1 Some contemporary pharmaceuticals of plant origin

Modern drug name	Therapeutic indications	Botanical name	Common plant name
Capsaicin	Topical analgesic	<i>Capsicum annum</i>	Red pepper plant
Cascara sagrada	Laxative	<i>Rhamnus purshiana</i>	Cascara sagrada
Colchicine	Gout; anti-inflammatory	<i>Colchicum autumnale</i>	Autumn crocus
Digoxin	Cardiac inotroph for heart failure/arrhythmia	<i>Digitalis purpurea</i>	Foxglove
Ephedrine and pseudoephedrine	Sympathomimetic/decongestant	<i>Ephedra sinica</i>	Mahuang
Methysergide	Vasoconstrictor for headaches	<i>Claviceps purpurea</i>	Ergot
Opiates (i.e., morphine, codeine)	Narcotic analgesics	<i>Papaver somniferum</i>	Poppy
Pilocarpine	Cholinergic agent used for glaucoma	<i>Pilocarpus jaborandi</i>	Jaborandi tree
Podophyllum	Antimitotic for venereal warts	<i>Podophyllum peltatum</i>	Mayapple
Quinidine and quinine	Antiarrhythmic/antimalarial agent	<i>Cinchona pubescens</i>	Quinine tree
Reserpine	Antidepressant	<i>Rauvolfia serpentina</i>	Rauwolfia
Senna concentrate	Laxative	<i>Cassia senna</i>	Senna
Taxol	Chemotherapeutic drug	<i>Taxus brevifolia</i>	Pacific yew
Vincristine and vinblastine	Chemotherapeutic drug	<i>Catharanthus roseus</i>	Madagascar periwinkle
Warfarin	Blood thinner for clots	<i>Melilotus officinalis</i>	Sweet clover
Yohimbine	Treatment of impotence	<i>Pausinystalia johimbe</i>	Yohimbe

herbalism. The United States, however, appears to be one of the last countries to embrace this practice of phytomedicine. The practice of phytomedicine has remained primarily outside the mainstream of contemporary American medical practice. Germany, the Orient, and several European countries (Italy, Spain, the Netherlands, Belgium, and others) have taken a more aggressive approach. Eighty percent of the world's population reportedly uses herbs for medicinal purposes (1). One of the most famous countries for this is Germany, which, by recent estimates, has allowed some 600–700 herbal products to be marketed in that country. Approximately 70% of German physicians now prescribe phytopharmaceuticals to their patients, which serves to maintain one of the world's largest markets for herbal drugs (2). Furthermore, the Commission E, a branch of German government somewhat similar to the U.S. Food and Drug Administration (FDA), has compiled therapeutic monographs for several hundred herbal medicines that discuss their general safety and efficacy.

Despite a sluggish start, the commercialized herbal industry is now blossoming in the United States. More than 500 different herbs are currently marketed in the United States, responsible for over 3.2 billion in sales in 1997(3). Limited regulatory guidelines and direct-to-consumer advertising have created a booming herbal market. Products are readily available in health food stores, supermarkets, and pharmacies, through mail-order catalogs, and via the Internet. Safety and efficacy data for these products are extremely limited. Varro E. Tyler, a well known author and researcher once said, "More

misinformation regarding the efficacy of herbs is currently being placed before consumers than at any previous time, including the turn-of-the century heyday of patent medicines." With the exceptions of the German Commission E monographs and some emerging studies, a critical evaluation of these entities is lacking. This presents both opportunities for research and challenges to modern science, medicine, and pharmacy.

TERMINOLOGY

Herbal products are considered a type of alternative medicine (e.g., herbal medicines, Chinese herbs, homeopathy, acupuncture, biofeedback, color therapy, music therapy, hypnotherapy, aromatherapy, Ayurvedic medicine, massage, therapeutic touch, Bach flower remedies, chiropractic, reflexology, naturopathy, and more). According to the Office of Alternative Medicine of the National Institutes of Health (NIH), characteristics of alternatives medicine include treatments that lack sufficient documentation in the United States for safety and effectiveness against specific disease and conditions and are not generally taught in U.S. medical schools or reimbursable by health insurance providers. Although uncertainty exists about the safety and efficacy of herbal products, there is even confusion about the terms used to describe such products. Some products are not herbs (i.e., saw palmetto is a tree) or botanicals (melatonin, glucosamine). Thus, further clarification is necessary.

Herbs are specifically defined as nonwoody, low-growing plants such as basil and parsley. Herbal medicine is considered to be the use of crude drugs of plant origin to treat illness or to promote health. A more correct term for this would be botanical medicine. Phytomedicinals are those common preparations, including capsules, tablets, tinctures, and fluidextracts that have been prepared from plant sources. This should be distinguished from plant-derived drugs that have been isolated, purified, and standardized from plant sources.

The words “natural” and “organic” are quite appealing to the consumer. Synthetic is often considered less desirable. Many believe that natural is better, safer, or not foreign to the body, but quite the opposite may exist. Native is identical to what is produced by or present in the body. Natural products refers to substances that are used to promote health or treat illness derived from plant, mineral, or animal sources. Organic refers to the level of pesticides or chemicals used in the growing process. For example, insulin from pork or beef sources is natural, but not native. Recombinant insulin is synthetic, but native. Thus, synthetic, as in synthetic insulin or estrogen, does not necessarily mean foreign or less desirable.

Two other broad terms that are used quite frequently are nutraceuticals and dietary supplements. Nutraceuticals include food, dietary supplements, and medical or functional foods that have a health or medical benefit including the prevention or treatment of disease. The newest term, introduced by the Dietary Supplement Health and Education Act of 1994 (DSHEA) is dietary supplement. A dietary supplement is neither a food nor a drug, according to the FDA. This term encompasses vitamins, minerals, herbs or other botanicals, amino acids, and any other dietary substance for use by humans to supplement the diet and promote health.

TRENDS IN HERBAL USE

The prevalence of alternative medicine use in the United States is steadily increasing. One may even describe the phenomenon as an explosion. A landmark survey published in 1993 estimated that 33.8% of Americans used one type of alternative therapy (4). A follow-up survey released in 1997 reported that frequency to be 42.1%, with 12.1% taking herbal medicine (5). In over 50% of the cases, use of alternative medicine was not supervised by the primary medical physician, and only 38.5% of consumers reported such use to their physicians.

Why do individuals seek alternative medicine? Many individuals are seeking health promotion and disease

prevention and believe that the “natural” way may be the best. For many people, conventional therapies may not be available or ineffective or may carry significant risk that the user may not be willing to accept. Some have tried several conventional therapies without relief and look to alternative medicine as the only remaining option. Additionally, extensive direct to consumer advertising and limited regulatory oversight have fueled the expansion of the alternative medicine industry.

Recent surveys have revealed some characteristics of alternative medicine consumers (5). Approximately 50% of consumers are between the ages of 35 and 49 and have a college-level education. Income levels exceeded \$50,000 for 48.1% of alternative medicine consumers. This may not be surprising because most insurance companies do not reimburse for such products. There appears to be a regional difference with use of alternative medicine, with over 50% of consumers living in the western portion of the United States. An earlier survey revealed that alternative medicine consumers were more likely to have one or more health conditions and less likely to be enrolled in an HMO. Furthermore, they had twice as many visits to traditional medicine providers and had a higher level of unmet medical need.

REGULATORY ISSUES REGARDING HERBALS

A major contention of the herbal medicine advocacy is the notion that because these entities are natural products, they are somehow safer and better for human consumption. However, the vast majority of alternative medicine products are essentially unregulated and not yet required to demonstrate efficacy, safety, or quality before becoming commercially available (6, 7). Currently, in the United States, there exists continued debate on what role the FDA should have in regulating and approving alternative medicines (7, 8).

The regulatory status of herbal medicine has changed over the past century. At one time, the United States Pharmacopeia, (USP), 1st Edition contained mostly herbal medicines. The first attempt by the U.S. government to regulate any “medicine” was the Food and Drugs Act of 1906, which simply prohibited the adulteration and/or misbranding of drugs. The act focused primarily on the quality of products being marketed but neglected the safety and efficacy of the medicines themselves. The Food and Drugs Act itself arose from public pressure imposed on the government after a series of fraudulent incidents involving patent medicine manufacturers and meat-packing firms were exposed and widely publicized.

The FDA was established by Congress in 1928, but it had been granted little authority and even less guidance with regard to how to proceed. The issue of product safety was finally addressed in the late 1930s after Elixir of Sulfanilamide contributed to the deaths of more than 100 people. With the 1938 Food, Drug and Cosmetic Act (FDCA), drugs were required to demonstrate safety before marketing. The FDCA defined drugs as substances, other than foods, that are recognized in *USP/National Formulary* and are intended to treat or prevent disease or affect body structure. In effect, herbs not included in the *USP/NF* were now considered food substances. Herbs that had been in the *USP/NF* were viewed as exempt and held official drug status until more recently.

As a result of Kefauver–Harris Amendment in 1962, drugs were required to demonstrate efficacy before marketing. The FDA presently regulates the pharmaceutical industry by requiring new product manufacturers to file a New Drug Application (NDA) for each new entity, which must include scientifically sound laboratory and clinical trials that demonstrate a drug product's safety and efficacy. Herbals and other products that lacked safety and efficacy data were considered over-the-counter agents. In 1972, panels were formed to evaluate the active components of these over-the-counter agents. The results of this effort were released in 1990. Products were classified as category I, II, or III. Category I products were generally recognized as safe and effective and were not misbranded. Category II and III substances were considered to be unsafe, ineffective, misbranded, or lacking sufficient data (7). Only a few herbals, such as senna, earned category I status. Because it was not cost-effective for most companies to present data, most substances now were considered foods or food additives that could not present labeling claims.

Although most herbals packaging could not be labeled with therapeutic claims, products continued to be sold with readily available literature, pamphlets, and advertisements touting the benefits of these substances. The Nutrition Labeling and Education Act of 1990 sought to improve labeling and education about food products and dietary supplements. At one point, there was even some consideration given to removing such products from the market. Concern over the ability to market herbal products led to extensive lobbying in Congress, which resulted in the Dietary Supplement, Health and Education Act of 1994 (DSHEA).

The DSHEA classified herbal products as dietary supplements intended to supplement the diet. Also included in the definition of dietary supplement were vitamins, minerals, botanicals, amino acids, and other

substances intended to supplement the diet. Dietary supplements were not considered foods or drugs and therefore were exempt for FDA oversight and the pre-market approval process. For all products introduced before October 1994, the burden of proof to demonstrate safety was now in the hands of the FDA and not in the hands of the manufacturer. Products introduced after October 1994 must be proven safe by the manufacturer. Manufacturers are currently not required to submit safety and efficacy data, and there are no good manufacturing standards (GMP) in place. However, the FDA does have the authority to establish GMP standards, and they are currently under development. Preliminary proposals indicate these GMP standards will more likely reflect GMP for food rather than for drugs.

The Office of Alternative Medicines (OAM) was also established at this time for the study and compilation of data on alternative medicines. The OAM functions within the NIH, and it is hoped that the OAM can further clarify the role of alternative medicines such as herbal remedies in this country. In other countries, similar committees (such as Commission E in Germany) have reviewed the safety and efficacy of herbs and published the results so that product debates can be resolved.

Although there is limited information regarding the therapeutic efficacy and standards for herbals some resources do exist. The most widely recognized source is the German E Commission E monographs, which contain information on more than 300 herbal products. Other well referenced resources include the *American Herbal Pharmacopeia*, the *British Herbal Pharmacopeia* (BHP), the *British Herbal Compendium*, the European Scientific Cooperative for Phytomedicines (ESCOP), the *U.S. Pharmacopeia*, and the World Health Organization (WHO).

At this time, consumers cannot be assured of purchasing a product that meets any regulatory standard, despite what may be listed on the label. Because they are derived from plant sources, the ability to standardize herbal content from lot to lot is confounded by many variables. Growing conditions, storage, harvesting, preparation, and processing all may affect the quality of the final product. Additionally, the actual active ingredient of many of these plant products may be unknown.

In review, alternative medicines have been exempted from demonstrating efficacy (Kefauver-Harris Amendment) by being classified as dietary supplements (Dietary Supplement Health and Education Act). This means that herbal products cannot make therapeutic claims on the label or package but may distribute third-party information regarding therapeutic claims, as long as this information is not misleading or product-specific.

LABELING ISSUES REGARDING HERBALS

Although the FDA lists many herbs as safe, herbal manufacturers cannot legally claim therapeutic efficacy of their product for a disease state without the evidence to support this claim. Dietary supplements may claim effects on structure and function of the body and may have authorized health claims. They cannot be labeled as intending to treat, prevent, mitigate, cure, or diagnose any disease. Dietary supplements may not be represented as food and cannot use the term “significant scientific agreement” when making a claim. Supplement manufacturers are required to have data on file to substantiate any “structure/function” claims that the manufacturer makes about the product. Examples of structure/function claims might include statements such as “helps you relax,” “supports prostate health,” “for liver maintenance,” or “helps promote cardiovascular health.” Claims that would not be allowed include such statements as “lowers cholesterol,” “improves benign prostatic hypertrophy,” or “treats immunodeficiency.” The FDA may ban dietary supplements if they pose an imminent hazard and may ban claims that are inherently misleading. Although the FDA regulates labeling, advertising of dietary supplements fall under the purview of the Federal Trade Commission. The FDA has suggested that manufacturers not make any claims with respect to their products and use in pregnancy. Additional rulings from the FDA are expected in the near future with respect to dietary supplements and their use in pregnancy.

THE MAKING OF A CRUDE DRUG

Approximately 250,000 species of flowering plants exist in the world today. Only a small percentage has been studied adequately for pharmacological activity. Based on past performance, it is reasonable to suggest that many valuable agents await being discovered in plants that we have not yet screened for therapeutic potential. Anecdotal reports of therapeutic efficacy and local folk medicine lore are a means to identify potentially valuable plant entities.

The term “pharmacognosy” refers to the study of chemicals from “natural” sources for medicinal application. Although this frequently refers to the study of chemical entities in higher plants, lower plants (fungi, molds, and yeast); animals; marine animals; fish; insects; and minerals are also fair game for evaluation of potential medicinal agents. In most industrialized nations, crude drugs (natural substances that are only collected and dried before manufacturing) are seldom used as the chief

therapeutic agent. Usually, important chemical constituents of the plant are identified, removed, derived, or modified and applied therapeutically in a consistent pharmaceutical vehicle in an effort to enhance the “natural” benefits and reduce any inherent risk.

Many plants can be grown in similar climates that resemble the plant’s native land. Compatibility of the plant to a particular region and the cost of harvesting the plant in that same area are two criteria that determine the availability of crude drugs in a particular country. Additionally, national and international restrictions on the collection of wild plants tend to limit availability of plant resources and escalate cost of production. These factors also force countries to specialize in producing only certain types of phytomedicinal resources.

Despite the tendency for a country to produce only certain phytosubstrates, the quality of crude drugs is often suspect. By the time a crude drug arrives at the manufacturing process, it has been exposed to various opportunities for adulteration, deterioration, and contamination.

During the collection or harvesting phase, skilled labor can be an important factor that influences quality of the harvest of wild plants. Deliberate adulteration most frequently occurs with expensive natural substances or natural substances in short supply. Mechanical devices may be more economical in the collection of some plants but may be of little use when only particular parts of another plant are desired. Cultivated plants ensure a more reliable source of the desired plant with less risk of substitution. Environmental conditions (temperature, rainfall, day length and sunlight, altitude, atmosphere, and soil) can dramatically affect quality, concentration, and presence of active constituents in plants. The age of the plant can also be an important determinant of the quality of active constituents in a crude drug.

At this stage, before drying, any insect-infested or disease-infested part of the plant should be removed. “Garbling” is the term for this semiskilled process of removing unwanted material (dirt, debris, and unnecessary plant parts) from the plant before drying and again before packaging and storage.

Drying can take from a few hours to a few weeks. This depends on the relative humidity of the local climate and the physical nature of the plant constituents. Drying by artificial heat (hot water pipes, stoves, and continuous belt dryers) carries the advantage of shorter drying times. Veterans of the process have learned when to stop the drying phase to prevent plant parts from becoming too brittle and overdried.

Deterioration of the dried product can occur as moisture from the surrounding air (usually approximately 10–15%)

and light return to the plant after drying. Return of moisture to the product provides a more favorable environment for contamination from molds, bacteria, and insects. Some processes introduce sterilization as a way to minimize microbial contamination. Proper storage and preservation must take place to ensure that quality of the product is maintained until delivery to the manufacturing facility where the crude drug undergoes a variety of grinding, crushing, extraction, and distillation procedures before being formed into an herbal pharmaceutical.

STANDARDIZATION OF DIETARY SUPPLEMENTS

Official standards are absolutely necessary to ensure the quality, reliability, and homogeneity of herbal products for consumers. Standardized products are paramount to those in healthcare planning to conduct clinical research with these products. Independent laboratories and university-affiliated research reports have documented the considerable variation that exists in terms of quality and reliability in these products. Abroad, the ESCOP, composed of manufacturers of herbal medicines and herbal associations, is working with European research groups to develop quality-control standards for the production of natural products. This committee is developing monographs for incorporation into such references as the *British Herbal Pharmacopoeia* and the *British Herbal Compendium*.

Likewise, in 1995, the USP commissioned an advisory panel on natural products whose mission was to establish standards and develop information concerning herbal or “dietary” supplements. Supplement monographs created by this endeavor address various issues associated with the standardization of individual herbals. The following list of section headings outlines the information found in each of the monographs:

1. Title—identifies the most commonly accepted name of the entity.
2. Definition—describes plant parts used, genus, species, authority, and family of the botanical.
3. Packaging and storage—cites appropriate packaging and storing conditions designed to promote integrity of the product.
4. Labeling—states requirements for label nomenclature.
5. Reference standards—identifies appropriate reference standards.
6. Botanic characteristics—describes visible and microscopic shape and structure characteristics of the whole plant or plant parts.

7. Identification—describes pharmacognostic tests useful in the identification of the entity.
8. Total ash—sets limits for the amount of inorganic residue remaining after incineration.
9. Acid-insoluble ash—sets limits for the amount of foreign inorganic residue remaining after boiling the total ash with 3N hydrochloric acid (an indication of how much dirt and soil remain in sample).
10. Water-soluble ash—sets limits for the residue remaining after boiling the total ash with water.
11. Foreign organic matter—limits the amount of nondrug-containing matter.
12. Loss on drying—sets criteria for loss limits of water, volatile oils, or other volatile chemical compounds.
13. Water content—limits variation in the water content of dried botanicals.
14. Alcohol-soluble/water-soluble extractives—sets thresholds for minimum acceptable amount of aqueous-, alcohol-, or aqueous alcohol-soluble extractives.
15. Volatile oil—describes the quantity of volatile oil present in the botanical.
16. Heavy metals—limits heavy metals present in the botanical.
17. Pesticide residue—sets strict limits of pesticide content.
18. Microbial limits—sets limits of total bacteria and mold count.
19. Marker substances and content tests—establish standards for quantitative chemical analysis of botanical for the presence of certain marker substances that aid in proper identification.

RISKS AND REALITIES OF HERBAL MEDICINES

Herbal drugs have many unknown and undocumented risks, side effects, and drug interactions. Like contemporary, rigorously tested pharmaceuticals, herbal medicines have some risk associated with their consumption. The fact that a plant is completely “natural” does not necessarily make that plant entirely risk-free. Several plants, when consumed in their most natural form, can cause grave illness or even death to humans and animals. A partial list of some of these natural herbal agents with the potential to harm is listed in Table 2. Herbalists, scientists, and the general public routinely avoid many of the plants listed in Table 2 because of their impending risks. However, hundreds of additional herbs and alternative medicines exist, much of their toxicologic profiles untested and undescribed. Adverse reactions with

Table 2 Examples of plants with the potential to harm

Common name	Botanical name	Reported toxic events
American mistletoe	<i>Phoradendron flavescens</i>	Hypertension and hypertensive crisis
American yew	<i>Taxus canadensis</i>	Cytotoxic
Arnica	<i>Arnica montana</i>	Violent gastroenteritis, nervous disorders, muscle weakness, collapse
Autumn crocus	<i>Colchicum autumnale</i>	GI toxicity, vomiting, neurologic toxicity, kidney failure
Belladonna	<i>Atropa beladonna</i>	Anticholinergic toxicity
Betal palm	<i>Areca catechu</i>	Teratogen
Bird's foot trefoil	<i>Lotus corniculatus</i>	Cyanide poisoning, convulsions, paralysis, coma, death
Bittersweet nightshade	<i>Solanum dulcamara</i>	Cardiac toxicity
Black nightshade	<i>Solanum americanum</i>	Cardiac toxicity
Black locust	<i>Robinia pseudoacacia</i>	Bradycardia, nausea, vomiting, dizziness
Bloodroot	<i>Sanquinaria canadensis</i>	Destroys tissue on application
Blue flag	<i>Iris versicolor</i>	Nausea, vomiting, and diarrhea
Broom	<i>Cytisus scoparius</i>	Diarrhea, GI toxicity/dehydration
Calabar bean	<i>Physostigma venenosum</i>	Cholinergic toxicity
Castor oil plant	<i>Ricinus communis</i>	GI toxicity/dehydration
Celandine	<i>Chelidonium majus</i>	
Chapparral	<i>Larrea tridentata</i>	Fulminant hepatic failure
Chinese lantern	<i>Physalis alkekengi</i>	
Comfrey	<i>Symphytum officinale</i>	Hepatotoxicity
Cotton	<i>Gossypium hirsutum</i>	Hypokalemia, male sterility, heart failure at high doses
Daffodil	<i>Narcissus pseudonarcissus</i>	CNS depression, miotic, coma, salivation, vomiting, death
Death camas	<i>Zigadenus elegans</i>	
Desert plume	<i>Stanleya pinnata</i>	
Ergot	<i>Claviceps purpurea</i>	Hallucinations, hypertension, tissue ischemia, St. Anthony's fire
Figwort	<i>Scrophularia nodosa</i>	
Foxglove	<i>Digitalis purpurea</i>	Bradycardia, heart block, arrhythmia
Goldenseal	<i>Hydrastis canadensis</i>	Hyperreflexia, hypertension, convulsions, respiratory failure
Green false hellebore	<i>Veratrum viride</i>	
Heliotrope	<i>Heliotropium europaeum</i>	Hepatotoxicity
Hedge mustard	<i>Sisymbrium officinale</i>	Cardiac toxicity, heart failure
Hemp dogbane	<i>Apocynum cannabinum</i>	Cardiac stimulant, arrhythmias
Henbane	<i>Hyoscyamus niger</i>	Anticholinergic toxicity
Horse chestnut	<i>Aesculus hippocastanum</i>	Bleeding
Indian pink	<i>Spigelia marilandica</i>	Overdoses have caused fatalities
Indian tobacco	<i>Lobelia inflata</i>	Vomiting, paralysis, hypothermia, collapse, coma, death
Jalap root	<i>Exagonium purga</i>	Dramatic purgative cathartic
Jimsonweed	<i>Datura stramonium</i>	Anticholinergic toxicity, hallucinations
Larkspur	<i>Delphinium ajacis</i>	
Life root	<i>Senecio longilobus</i>	Hepatic failure from hepatic veno-occlusive disease
Lily of the valley	<i>Convallaria majalis</i>	Cardiac toxicity
Marsh marigold	<i>Caltha palustris</i>	Second most common killer of livestock (accidental ingestion)
Mayapple	<i>Podophyllum peltatum</i>	Severe GI irritation
Monkshood, wolfsbane	<i>Aconitum</i> spp.	Cardiotoxicity, neurotoxicity, hypotension, arrhythmias
Moonseed	<i>Menispermum canadense</i>	Tachycardia, severe vomiting, purging
Morning glory	<i>Ipomoea purpurea</i>	Potential for hallucinations/psychosis
Mountain laurel	<i>Kalmia latifolia</i>	
Periwinkle	<i>Vinca major, vinca minor</i>	Cytotoxicity, renal failure, hepatic failure, neurological damage
Poison hemlock	<i>Conium maculatum</i>	Birth defects, "crooked calf disease"
Pokeweed	<i>Phytolacca americana</i>	
Queen's delight	<i>Stillingia sylvatica</i>	GI toxicity, mutagenic
Red baneberry	<i>Actea rubra</i>	

(Continued)

Table 2 Examples of plants with the potential to harm (*Continued*)

Common name	Botanical name	Reported toxic events
Rosebay rhododendron	<i>Rhododendron maximum</i>	
Strychnine tree	<i>Strychnos nux-vomica</i>	CNS stimulation leading to seizures and cardiac arrest
Tall buttercup	<i>Ranunculus acris</i>	
Wallflower	<i>Cheiranthus cheiri</i>	Cardiac toxicity, heart failure, bradycardia
White false hellebore	<i>Veratrum album</i>	
Wild cherry	<i>Prunus virginiana</i>	Dyspnea, vertigo, convulsions
Wild licorice	<i>Glycyrrhiza lepidota</i>	Hypotension, hypernatremia, hypertension, muscle weakness
Wintercress	<i>Barbarea vulgaris</i>	Renal damage in animals
Wormseed	<i>Chenopodium ambrosioides</i>	Nausea, dizziness, convulsions, paralysis
Wormwood	<i>Artemisia absinthium</i>	Rhabdomyolysis, renal failure, seizures, "absinthism," mental doze
Yellow jessamine	<i>Gelsemium sempervirens</i>	Paralysis and death

herbal medicines can be directly related to exposure of chemical components of the plant (intrinsic) or to inappropriate or incorrect manufacturing/production procedures during preparation of a dietary or herbal supplement (extrinsic)(9). Drug interactions, toxicity from high concentrations, or undesirable effects from simple ingestion of the chemicals of the herbal supplement are considered typical intrinsic misadventures.

Although laws do not require reporting of adverse events of dietary supplements to the FDA at this time, many untoward events have been documented. The FDA has created MEDWATCH [(800) FDA-1088] to receive and compile reports of adverse reactions from pharmaceuticals. Healthcare providers are encouraged to report to this organization any and all adverse events related to dietary supplements and their consumption.

A review of adverse events related to herbal medicines reported in the medical literature from 1992 to 1996 has been compiled (10). This report highlights cases of hypersensitivity reactions, hepatotoxic reactions, and various types of renal damage associated with various herbal products. Some Chinese herbal preparations appear to be notorious for causing nephropathy (11–13). One of the more infamous adverse events related to the consumption of a dietary supplement was associated with the amino-acid L-tryptophan, touted for its ability to reduce pain and promote sleep. During the late 1980s, it was discovered that excipients or tablet "fillers" contained in a few L-tryptophan products caused a rare, but reportedly fatal, syndrome (eosinophilia-myalgia syndrome). Additionally, popular dietary supplements and weight-loss products containing ephedra alkaloids have become a recent cause of adverse effects (e.g., increased blood pressure, tremor, arrhythmia, seizure, stroke, heart attack, and death), as supported

by several hundred incident reports to the FDA between 1993 and 1997 (14). Furthermore, a study designed to assess the prevalence of herbal product use and its associated morbidity in a population of adults with asthma found an increase in the number of hospitalizations attributed to patients who self-medicated with herbal products and black coffee or tea (15). In a large retrospective study of admissions to a Taiwan hospital, 4% were found to be drug-related. Herbal medications ranked third as the drug category most responsible for adverse effects (16).

Herbal-Drug Interactions

Potential drug interactions are usually either unknown or unconsidered. Many herbs contain naturally occurring coumarins and cardiac glycosides, chemicals that potentiate hypoglycemia or hyperglycemia and promote sedation, or various other actions that can endanger the lives of patients taking prescription medications. Recently, two reports strongly suggest that a potential drug interaction exists between some drugs when used in combination with St. John's Wort (17, 18). It appears that St. John's Wort may act as an enzyme inducer of the cytochrome P-450 system. Subsequently, drugs that undergo metabolism by the CYP-450 3A isoenzyme must be used more cautiously when taken in combination with St. John's Wort. Not surprisingly, metabolism-oriented interactions are not the only type of drug interactions reported with herbal medicines. A case report of malabsorption of levothyroxine has been reported because of the ingestion of a combination herbal remedy (19). Some recent reviews cite potential risks related to herb-anesthesia interactions and other preoperative concerns with herbal medicines (20).

Propagation of Herbal Medicine Misinformation

Inadequate or inappropriate dissemination of information to the lay public, combined with less-than-stringent regulation, leads unwary consumers down the path of dangerous adverse events related to the consumption of herbal medicines. Successful dietary supplement and herbal manufacturers spend several million dollars each year on advertising. Existing regulations and product labeling of herbal supplements fail to provide ample warning of risks to consumers. In many cases, product advertising could be considered misleading, or at least questionable, despite FDA restrictions to limit manufacturer claims that relate only to proper health maintenance (10). The awesome marketing power of the Internet has by far the greatest potential to magnify and express the unknown dangers of herbs, if information regarding commercialization and marketing of alternative medicines is left unreviewed. Herbal products otherwise unobtainable in the United States have been purchased over the Internet and have been associated with substantial morbidity in uninformed consumers (21).

Misbranding, Substitution, Contamination, and Adulteration

Generally, dietary supplement and herbal medicine manufacturers are not required to meet the same standards and regulations that apply to the pharmaceutical superpowers.

In the spring of 1998, the FDA issued a warning regarding an herbal medicine called *Sleeping Buddha*. Apparently, the product contained an unlabeled sedative, the benzodiazepine estazolam. Fortunately, no misadventures with this product were reported. At about the same time, the FDA issued another warning regarding an herb called plantain. This plant contains digitalis-like glycosides and, therefore, consumption could be problematic for elderly patients or patients with cardiac disease. Potential dangers of this sort fall in the category of extrinsic misadventures. These are usually related to a lack of standardization, contamination, adulteration, or substitution of the products, in addition to either misidentification or misbranding of the supplement. Additionally, adulteration of Chinese herbs with mefenamic acid has been responsible for cases of herbal nephropathy (12). A more detailed discussion of misbranding, adulteration, and the like has already been published (9).

Many plants can vary considerably as to their quantities of active chemical constituents. This variability may depend on the time of year of harvest; age of the plant; method of pollination; and/or conditions of watering,

wind, weather, and soil. These variables can lead to considerable differences in the finished product after manufacturing.

Additionally, consumers are often exposed to a variety of compounds when they ingest herbal supplements. Supplement manufacturers do not always separate out the active chemical ingredients of the plant; subsequently consumers ingest many different chemicals that occur “naturally” in the plant along with the reportedly active constituent.

Additional concerns arise from the notable lack of stability testing of the product, because these data are usually not available on the label or otherwise. Various contaminants (i.e., heavy metals, aspirin, caffeine, theophylline, diuretics, corticosteroids, benzodiazepines, atropine, and others) have been discovered in reportedly “pure” herbal products (10).

Lack of Consensus on Usage and Monitoring

There exists an overwhelming lack of consensus as to how an herbal medicine should be ingested or applied therapeutically. Recommended doses vary considerably from source to source, even among noted advocates in the field. No standards exist for monitoring adverse events or effectiveness.

Delay in Time to Proven Therapy

The time an individual spends evaluating a desired response from an herbal supplement could be spent seeking professional medical advice and proven pharmacotherapy. In cases such as severe depression, extreme mental illness, or other life-threatening diseases, the delay in seeking professional help could be the difference between life and death.

Abuse of Herbal Medicines

Unlike their prescription-only counterparts, herbal medicines can be purchased and consumed freely by virtually anyone. This can take place without forethought or advice, without restriction or limitation, without even something as insignificant as confirming a person's age or identification. Yet, in stark contrast, we require that individuals be of a certain age before purchasing cigarettes or alcohol. Individuals wishing to purchase these chemicals must be able to demonstrate proof of the minimum age requirement by displaying a valid identification card. This is likely required of minors because society believes they are not mature enough and perhaps

lack “sufficient education” before the designated age to handle the potential dangers and responsibilities that accompany use of chemicals (cigarettes and alcohol) that can intoxicate, addict, or even cause physiological damage. Herbal medicines, like cigarettes and alcohol, are not without the potential for abuse, the potential to harm, and in some cases, the potential to addict or intoxicate. A similar corollary to the minor purchasing cigarettes or alcohol can be envisioned, analogous to a uninformed or misinformed consumer purchasing herbal medicines.

One such example is the opium poppy plant, which has been used to treat pain for centuries. Its derivatives continue to be used in modern medicine, yet its potential for abuse is also well documented. No one would argue that this plant should be regulated because of its potential for abuse. The same can be said of the leaves of the coca shrub, which have been chewed by the Incas and their descendants for countless generations to help them work in the high altitudes of the Andes Mountains. In many cultures, traditional healers and religious leaders have used psychoactive plants as part of their rituals, yet the perception remains that plants are safe and pose no danger for abuse or dependence. Many plants may have been safely used for hundreds of years in controlled settings such as religious rituals, but when used indiscriminately by the general public, they can lead to problems. A good example is the herbal anxiolytic kava, which is currently being promoted heavily. It has been used traditionally in Polynesia for hundreds of years without any reported adverse consequences, yet it is now known to increase the effects of alcohol and even by itself can lead to intoxicating effects (22–24). Its users continue to consume kava even after they develop adverse effects such as the skin reaction, which can occur from chronic use. Like many drugs with abuse potential, not everyone abuses a substance to the same degree. However, as its use becomes more prevalent, more and more cases of misuse will continue to appear. The abuse potential of many drugs is not identified immediately but rather after controlled clinical trials. Unfortunately, as noted above, herbal products do not have to undergo these rigorous trials before being marketed and thus problems can be identified only after many people experience an adverse effect such as dependence.

Cost

Although herbal medicines tend to be less expensive than their FDA-labeled counterparts, the cost can still be substantial if examined over several weeks to months. Costs related to delayed effective therapy, side effects, drug interactions, and hospital admissions might also be considered in this regard. As herbal medicine becomes

more popular and as herbal medicine manufacturers spend more and more on advertising, the margin of cost difference between the two types of drugs will diminish.

SPEAKING THE LANGUAGE—A BRIEF LOOK AT SOME “ALTERNATIVE” TERMINOLOGY

In this section, we define some terminology commonly used when discussing alternative medications. Throughout the Encyclopedia, we have attempted to replace this terminology with more readily recognizable medical terms. However, in the event that the reader comes across an unfamiliar term, we hope to have included the definition for that term here in this section. We have made some assumptions as to what we thought might be unknown by the average healthcare practitioner not skilled in alternative medicine. *The information contained in this section is purely informative and not meant to be instructional or considered factual in any way.*

Alternative Remedy Formulations

Compresses and poultices

A compress is clean linen soaked in an infusion or decoction, whereas a poultice is a solid material (powdered or fresh dried herb, often fashioned into a paste), that is then typically placed over a wound in an effort to accelerate the healing process. In some cases, a covering of wax paper and warmth from a hot water bottle is thought to be beneficial.

Decoctions

A decoction is a water-based preparation, much like a tea. Its use is thought to be more potent with hard, woody plants that require higher heat to release their active constituents. Dried herb is placed into boiling water for 10–15 min and then strained before consuming.

Extracts

Extracts are concentrated solutions—occasionally concentrated solid or powdered extracts are produced—of chemical constituents of the plant. These are obtained using alcohol-based (organic) or water-based (aqueous) solvent extraction of the plant, after which the solvent is partially or completely removed from the solution.

Infusions

Making an infusion is essentially synonymous with making a tea. Infusions can be hot or cold and are particularly favored for chemical compounds that are thought to be heat-labile. Leaves, flowers, or tender stalks

are often prepared for consumption using this process. The solution is typically strained free of debris before consumption. This type of infusion is not to be confused with a sterile intravenous infusion administered in contemporary medicine.

Tinctures

These are a form of weakly concentrated alcoholic extract of a plant. Occasionally, vinegar or glycerin extracts have been used. Tinctures typically do not need heat to help extract active constituents of the plant, but they do need the solvent and a longer period to extract the active ingredients.

Alternative remedy therapeutic effects (not necessarily proven) include:

1. Alteratives—otherwise known as “blood cleansers,” which promote health and vitality.
2. Adaptogens—enable the body to deal with stress more effectively.
3. Anticathartics—help the body remove edema, congestion, and mucous, typically associated with sinus and respiratory infections/conditions.
4. Astringents—shrink and toughen skin cells, reduce secretions and discharges.
5. Bitters—Supposedly stimulate digestion through “taste sensation.”
6. Carminatives—serve to promote normal bowel function by stimulating peristalsis and “relaxing” the gastrointestinal tract.
7. Cholagogues—stimulate secretion of bile from gallbladder, also produce a laxative effect.
8. Demulcents—internal use soothes and protects inflamed/irritated tissue.
9. Emmenagogues—promote normal menstrual flow.
10. Emollients—external application soothes and protects inflamed/irritated skin.
11. Galactagogues—increase lactation in breastfeeding women.
12. Sialagogues—stimulate flow of saliva.
13. Styptics—stops external bleeding through “astringent” properties.
14. Tonics—agents that “strengthen” an organ or organ system.

Chemical Constituents of Plants

Alkaloids

These naturally occurring nitrogen-containing chemicals (amines) have very diverse pharmacological effects. Examples include codeine, morphine, caffeine, and emetine.

Anthraquinones

Constituents that typically exhibit laxative effects. Examples are aloin, emodin, barbaloin, rhein, and chrysophanol.

Bitter principles

Diverse in structure, these include iridoids and terpenes thought to promote normal bowel function.

Coumarins

These are naturally occurring anticoagulants.

Flavonoids

Examples include vitamin P and hesperidin. They perform a wide range of activities.

Glycosides

Sugar-containing compounds, glycosides perform various activities. Examples include digitalis glycosides, sennosides, and cascariosides.

Phenols

Phenols are weak acids that exhibit analgesic and antiseptic properties. Examples are salicylic acid and eugenol.

Saponins

These are constituents that form foams when agitated in water-based solutions. They are thought to have antiinflammatory, hemolytic, and expectorant effects. Saponins are found in extracts of yucca, sarsaparilla, alfalfa, fenugreek, licorice, and ginseng.

Tannins

Tannins have astringent properties but have the potential to produce liver damage at high concentrations. They are thought to be useful in the treatment of burns and wounds.

Volatile oils (essential oils)

Composed of complex organic compounds (phenols, acids, alcohols, ethers, ketones, and aldehydes), volatile oils evaporate when exposed to air. Volatile oils are found in many plants and may produce the aroma of the plant. Volatile oils exhibit various properties; but some common oils are antiseptic or local irritants, or sedative. Oils of peppermint, clove, cinnamon, garlic, and thyme are volatile oils.

SUMMARY

Precedent suggests it may be foolish to ignore promising chemical constituents in the herbal compendium. Experts

in pharmacognosy (the study of drugs that originate from plant and animal systems) suggest that only a small percentage of plants have been thoroughly investigated for pharmacological activity. Today's major pharmaceutical companies appear to have forgotten this fertile reservoir of unique chemical entities in favor of spin-offs of existing successful agents and new compounds in biotechnology. Our previous practice of developing new medicines from plants has helped many people and, in some cases, brought about the synthesis of even more valuable compounds than those taken directly from the plant itself. With global public interest in the area of alternative and complementary medicine at an all-time high, it is imperative for the safety of patients that we investigate these compounds thoroughly and provide relevant clinical data with respect to herbal medicines and their derivatives. Pharmaceutical companies may wish to redirect some attention toward these botanical chemicals. Patients can only make informed decisions about their health care if indeed healthcare providers themselves are truly informed.

POLAROGRAPHY AND VOLTAMMETRY

A. David Woolfson

The Queen's University of Belfast, Belfast, United Kingdom

INTRODUCTION

Voltammetry is a term that encompasses all measurements based on controlled electrolysis at a microelectrode. Polarography, first introduced by the Czech electrochemist Jaroslav Heyrovsky in 1922, is voltammetry at a special form of mercury microelectrode, the dropping mercury electrode (DME). Mercury electrodes can only be driven to negative potentials because otherwise, the metal dissolves in aqueous solutions as Hg^{2+} . Consequently, polarography is an electroanalytical method based on the cathodic reduction of electroactive species, either metal cations or electroreducible organic species, in an electrically conducting solution. By contrast, voltammetry is based on electroanalysis involving anodic oxidation, preferably in a flowing system in which a self-cleaning action prevents fouling of the solid electrode surface by the products of the electrochemical reaction, thereby leading to nonreproducible current/voltage curves.

HISTORICAL BACKGROUND OF POLAROGRAPHY AND VOLTAMMETRY

The determination of electrocapillary curves for mercury, a phenomenon attributable to changes in the surface tension of the liquid metal as a function of applied potential in an electrolyte solution, was known from the beginning of the 20th century. An electrode consisting of mercury dropping from a fine glass capillary was devised for this purpose. However, secondary maxima appeared at certain points on the electrocapillary curves. The origin of these distortions to the electrocapillary curve was unknown at that time, and it was this phenomenon that Heyrovsky originally sought to investigate and explain. He noted that when certain cations were added to an electrolyte solution, kinks appeared on the electrocapillary curves at potentials close to the values for known electrochemical processes at the DME. The applied voltage between the DME and a mercury pool formed at the bottom of a cell containing an aqueous metal ion solution was gradually increased. Under these conditions,

the resulting current had a small initial value that began to rise rapidly in a reproducible manner as the voltage scan progressed. The point at which this rapid rise in current occurred, the threshold potential, depended only on the species of metal ion present in the test solution. The rapid current rise increased linearly with an increasing applied voltage until the current eventually became constant again. This constant current value, which was found to be proportional to the concentration of metal ion in solution, forms the quantitative basis of polarographic/voltammetric analysis. The method by which Heyrovsky obtained the current voltage curve at the DME involved gradually increasing the applied external voltage (the voltage scan), measuring the corresponding mean current, and plotting this current against the applied voltage. This method constitutes analytical polarography, sometimes referred to as classic or direct current (d.c.) polarography to distinguish it from more modern variants. Heyrovsky was awarded the Nobel Prize in 1959 for his work on the discovery and development of polarographic analysis.

Classic d.c. polarography was limited in its development by the unreliability of early polarographs (instruments used to record current versus applied voltage curves), and the difficulties inherent in operating what were, at that time, relatively complex instruments. Although the method was suitable for metal cations, analytical applications in the field of electroactive organic compounds were restricted by the problem of the higher electrical resistance of nonaqueous solvent systems. Thus, only a water or water-alcohol system could be used with a conventional polarographic cell making up a two-electrode system of DME and reference electrode. Furthermore, determination of metals could be achieved at great sensitivity with spectroscopic methods such as flame emission and atomic absorption spectroscopy. This situation generally remained unchanged until the late 1950s, when modified polarographic techniques, such as square-wave, pulse, and a.c. polarography, began to appear, facilitated by the development of solid-state electronics. The development of a three-electrode system, linked to an electrical circuit known as a potentiostat, overcame the high resistance associated with the use of nonaqueous systems and widened the analytical applicability of the polarography. These developments,

which form the basis of modern polarographic and voltammetric analysis, including their applications to the pharmaceutical sciences, have been referred to as the “renaissance” in polarography (1).

THEORY OF POLAROGRAPHY AND VOLTAMMETRY

In a simple electrolysis experiment in which an electrolyte solution is electrolyzed between two platinum plate electrodes, an anode and a cathode, efficient stirring of the solution is necessary to drive ions toward the electrodes. When the potential difference between the two electrodes, which is a function of the applied external voltage, is sufficiently high, ions are discharged at the electrode surfaces. Such electrodes are working electrodes. The current flowing caused by ion discharge is an electron transfer or faradaic current, i.e., a current attributable to transfer of electrons to the electrode (anodic oxidation) or gain of electrons from the electrode (cathodic reduction). This faradaic current continues to flow until all of the electroactive species is consumed by electrolysis (Fig. 1A). Replacement of a platinum plate electrode with a platinum wire microelectrode and use of a quiet (unstirred) solution result in the electrolysis current reaching a limiting value (Fig. 1B).

The current interest in polarography is attributable to electron transfer between the electrode and the electroactive species. Therefore, the limiting current must be proportional to the concentration of the electroactive species in the bulk solution. This remains true provided the electroactive species can only reach the electrode surface by diffusion along a concentration gradient. The concept of a limiting diffusion current is central to quantitative analysis by polarography or voltammetry. However, the magnitude of this limiting current is nonreproducible because the electrode surface becomes fouled easily by the products of the electrochemical reaction. To overcome this problem, a microelectrode with a renewable surface is required. Use of a microelectrode ensures that an infinitesimally small proportion of the bulk electroactive species is consumed in a single polarographic run, making the technique essentially nondestructive of the analyte.

Suitable working electrodes for voltammetry are those that can be driven to take up a new potential in response to an applied external voltage, a process known as electrode polarization. Reduction or oxidation of an electrochemically active species at a working electrode results in depolarization of the electrode. The word depolarizer is therefore sometimes used to describe an electrochemically active species. In voltammetry, the working electrode may

Fig. 1 Comparison between electrolysis and limiting currents. (A) A faradaic electrolysis current between platinum plate electrodes at an applied voltage beyond the threshold potential of the electroactive species. (B) Effect of replacing the platinum plate electrodes with platinum wire microelectrodes. In the absence of stirring, the current reaches a limiting value rather than increasing linearly with an increasing applied voltage.

be fabricated from metals such as gold or platinum, various forms of carbon, or metallic mercury.

The use of mercury dropping from the tip of a fine glass capillary (the DME) as the polarizable electrode has certain specific advantages. Most important, however, the electrode surface is reproducibly renewed as each succeeding drop is formed at the capillary tip. Electrical connection to the DME can be made using a brass post projecting through the glass capillary and contacting the liquid mercury column. The primary disadvantages of mercury as an electrode relate to environmental and safety concerns, difficulties in using mercury in flowing systems (although this is now possible to some extent), and its restriction to electroactive species amenable to cathodic reduction rather than to anodic oxidation. Problems of safety and practicality can be solved through the use of a multimode electrode polarographic/voltammetric electrode assembly. This replaces the classic DME and can

also generate a hanging mercury drop electrode (HMDE.) for use in stripping analysis, in addition to the intermediate static mercury drop electrode (SMDE). Multimode electrodes also offer replacement electrode assemblies for non-DME voltammetric applications in both quiet and stirred solutions. Rotating electrode designs can also be accommodated. For mercury electrodes, the multimode electrode is compact and does not require the gravitational force of the mercury column to extrude the drop. Rather, the drop is formed pneumatically, using nitrogen gas pressure. The mercury is hermetically sealed, an important safety consideration, and only a few milliliters are required for up to 200,000 drops without the need for refilling.

Classic d.c. Polarography

In classic polarography at the DME, as with classical electrolysis, the electrochemical reduction occurs when the applied potential becomes sufficiently negative, i.e., when the applied potential exceeds the threshold value for a given depolarizer. The applied potential is in the form of a linearly increasing voltage ramp with a typical slope of between 2 and 10 mV s⁻¹. Unlike electrolysis, however, the current resulting from application of the ramp voltage does not continue to increase indefinitely until all the electroactive material is consumed. Rather, the current reaches a limiting value represented by the plateau in Fig. 2. This current is limited because when the applied potential is sufficiently negative, the rate of electron transfer becomes instantaneous and exceeds the rate of supply of the depolarizer to the electrode surface. Because the depolarizer can reach the electrode surface only by diffusion along a concentration gradient, the process is said to be diffusion-limited, and the resulting electron-transfer current is the limiting diffusion current, i_d (Fig. 2). The limiting diffusion current is directly proportional to the analyte concentration in the bulk solution.

The electroactive species can also reach the electrode surface by migration under the influence of the electrical field between the electrodes. This gives rise to a migration current that is not diffusion- and, therefore, concentration-dependent. This migration current must be eliminated by providing an excess of charge carriers in the solution that are not discharged within the working potential range of the experiment. Various salt solutions may be used for this purpose. More conveniently, because electrochemical reactions are often pH-dependent, a buffer solution may be used. This solution is variously referred to as the base, inert, or supporting electrolyte. Therefore, although the ions of the supporting electrolyte will move through the solution and carry charge, no current will flow in the external circuit because no faradaic process will occur in the absence of a depolarizer.

The electroactive species can also reach the electrode surface by convection, giving rise to a convection current that is, again, nonconcentration-dependent. Convection effects are attributable to stirring of the solution or, less frequently, to thermal currents. Thus, polarography and voltammetry are carried out in quiet (unstirred) solutions.

The concentration-dependent mass transport process, when other mass transport processes have been eliminated, is diffusion of the electroactive species toward the electrode surface along a concentration gradient. As the electroactive species approaches the surface of the DME, it will be electrochemically reduced. Thus, in a narrow solution layer, the diffusion layer, immediately adjacent to the drop surface, there will be a lower concentration of the electroactive species than that present in the bulk solution, giving rise to the concentration gradient. It may be shown from Fick's law of diffusion that for an electroactive species diffusing across a thin diffusion layer of thickness d , the diffusion current, i_d , will be given by Eq. 1.

$$i_d = n \cdot F \cdot A \cdot D \cdot (C - C_i)/d \quad (1)$$

where D is the diffusion coefficient of the electroactive species, F is Faraday's Constant, A is the drop surface area, n is the number of electrons transferred per molecule of depolarizer, C is the bulk concentration of the depolarizer, and C_i is its concentration in the diffusion layer.

As C_i approaches zero, the rate of diffusion becomes proportional to the concentration of depolarizer in the bulk solution. Beyond the threshold potential, the electron transfer reaction will be initiated, and, as the potential is gradually increased, the rate of this reaction will continue to increase until it exceeds the rate of supply of the depolarizer to the electrode surface by diffusion, with all other mass transport processes having been suppressed. Under these conditions, the diffusion process becomes the rate-limiting step, and the resulting faradaic current, i_d , is now said to be the limiting diffusion current. Because i_d is measured over many individual drop lifetimes, it is properly described as the average limiting diffusion current and is given by Eq. 2, where i_d and C are the only variables.

$$i_d = n \cdot F \cdot A \cdot D \cdot C/d \quad (2)$$

The limiting diffusion current is described quantitatively by the Ilkovic equation (Eq. 3).

$$i_d = 708 \cdot n \cdot D^{1/2} \cdot m^{2/3} \cdot t^{1/6} \cdot C \quad (3)$$

where m is the rate of flow of mercury from the DME in mg s⁻¹ and t is the drop lifetime in seconds. D has units of cm² s⁻¹, C is expressed as mM l⁻¹, and i_d is expressed in mA.

Fig. 2 Classic d.c. polarogram of diazepam (20 mg ml^{-1}) in 0.1 M sulfuric acid as the supporting electrolyte. Region A is the background current attributable to the supporting electrolyte, region B shows the rising faradaic current as it reaches a limiting value, and region C is the cut-off point at which the current goes off scale caused by the reduction of hydrogen ions.

Electrical Double Layer

When only the inert electrolyte is present in the polarographic cell a residual current will still flow. This current, which is nonfaradaic, is attributable to the formation of an electrical double layer in the solution adjacent to the electrode surface (Fig. 3). At all applied potentials, a

current flows to develop this double layer, and the process may be considered analogous to the charging of a parallel plate capacitor. Therefore, the charging current is a capacitance current and varies during the drop lifetime, i.e., with the size of the mercury drop. When the drop surface area is increasing rapidly from the start of the drop lifetime, the capacitance current is a maximum, falling to a

Fig. 3 The electrical double layer at a mercury drop shorted to a reference electrode and with no external applied potential.

minimum near the end of the drop lifetime when the drop size is at a maximum and the surface area of the drop is momentarily constant. The magnitude and direction of the capacitance current vary with the applied potential because of the variation in the surface tension of mercury with electrode potential. When the mercury drop is at its maximum surface tension, there is effectively no electrical double layer at the drop surface and, therefore, no capacitance current, a point known as the electrocapillary maximum. Beyond this potential, the capacitance current changes direction as the double layer is reversed, with the mercury drop now possessing a negative charge. The practical consequence of this is to impose the familiar serrated pattern on the polarographic wave (Fig. 2).

Mechanisms of Electrode Processes

The shape of the polarographic wave is further influenced by the nature of the electrode process occurring at the drop surface. Polarographic waves may be reversible, irreversible, or quasireversible. The overall electrode process comprises the diffusion, electron transfer, and electrochemical reaction steps.

Reversible processes are those that attain thermodynamic equilibrium at every instant of the drop life owing to rapid electron transfer. Reversible processes give rise to well-defined d.c. polarograms, and diffusion control is always the determining factor. Irreversible processes are so slow that equilibrium is not attained during the drop lifetime, and d.c. polarograms dependent on such processes often show poor definition. The rate-controlling step may be either the electron transfer process or the

subsequent chemical reaction. Many organic reductions at the DME, however, fall into an intermediate category, quasireversible processes. Whereas the rate constant for the reverse reaction will be negligible for a wholly irreversible reaction, it has an intermediate value for quasireversible reactions. Such reactions are normally seen only with longer drop times of at least 3 s.

The reversibility, or otherwise, of an electrode process is best investigated using the technique of cyclic voltammetry (2), in which a rapid forward and reverse voltage ramp is applied in triangular form (Fig. 4A) to interact with both the electroactive substance and its reduction product that, for quasi- or fully reversible processes, may be oxidized back to the starting material, giving the characteristic waveform shown in Fig. 4B. The separation between anodic and cathodic peaks indicates whether the electrode process is quasi- or fully reversible. Additional mechanistic investigations can also be made in respect to the number of electrons involved per molecule

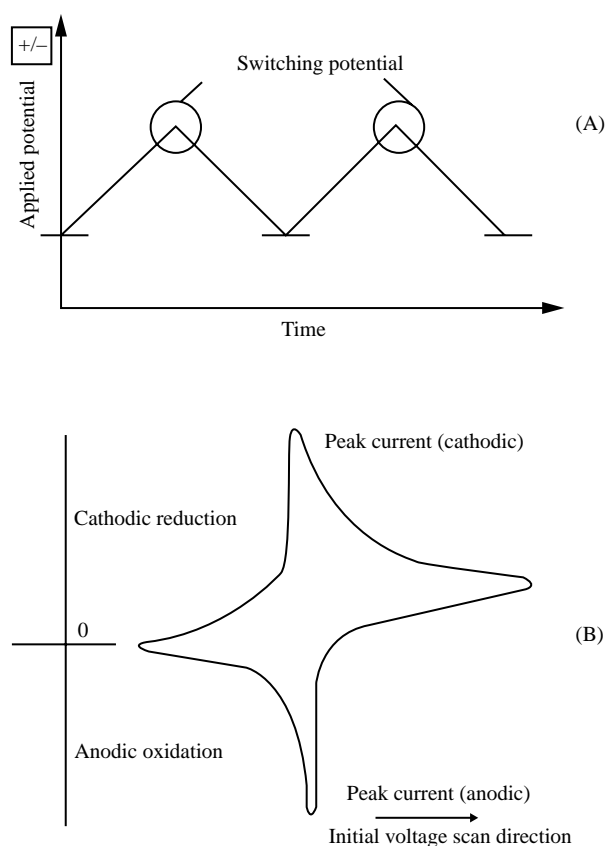

Fig. 4 Cyclic voltammetry. (A) Voltage waveform showing the rapid forward and reverse voltage sweeps. (B) Typical cyclic voltammogram for completely reversible system.

in the electron transfer process, a factor that can be determined by controlled-potential coulometry (3).

Effect of Oxygen in Polarography

In polarography, but not in anodic voltammetry, it is necessary to provide a facility for removing oxygen from the electrolyte solution in the polarographic cell. This is normally achieved by bubbling oxygen-free nitrogen through the solution for 10 min before starting the voltage scan. The surface of the solution is then blanketed by oxygen-free nitrogen during the polarographic run to prevent ingress of additional oxygen from the atmosphere. Removal of oxygen is necessary because the dissolved gas is polarographically active and can mask the analytical signal of interest in certain potential regions.

MODERN POLAROGRAPHIC AND VOLTAMMETRIC METHODS

In classic d.c. polarography, the actual current measured comprises the limiting diffusion current, together with current components, because of background electrical signals and, more important, the current charging the double layer capacitor at the electrode surface. Classic d.c. polarography is in many ways best suited to the elucidation of electrode processes. It lacks sensitivity for modern analytical purposes, and the sigmoidal current/voltage curves are difficult to measure. Modern polarographic and voltammetric methods are now available (Fig. 5) in which these problems have generally been resolved, producing an analytical technique with much enhanced sensitivity and a more easily interpretable current–voltage waveform.

Current-Sampled d.c. Polarography

Current-sampled polarography is a modern variant of the original *tast* (from the German “to touch”) polarography, a method that involved the measurement of the polarographic current only at a fixed time interval during each drop lifetime. This was originally accomplished by the use of a mechanical touching contact (4) but is achieved in modern instruments using a digital approach in which the current is electronically sampled at a precise moment, typically 20 ms, near the end of the drop lifetime when the area of the drop is effectively constant. For this purpose, the drop lifetime is precisely and mechanically controlled by the instrument rather than being gravity-dependent, a feature shared by other modern methods. Current-sampled polarography produces a smooth polarogram by

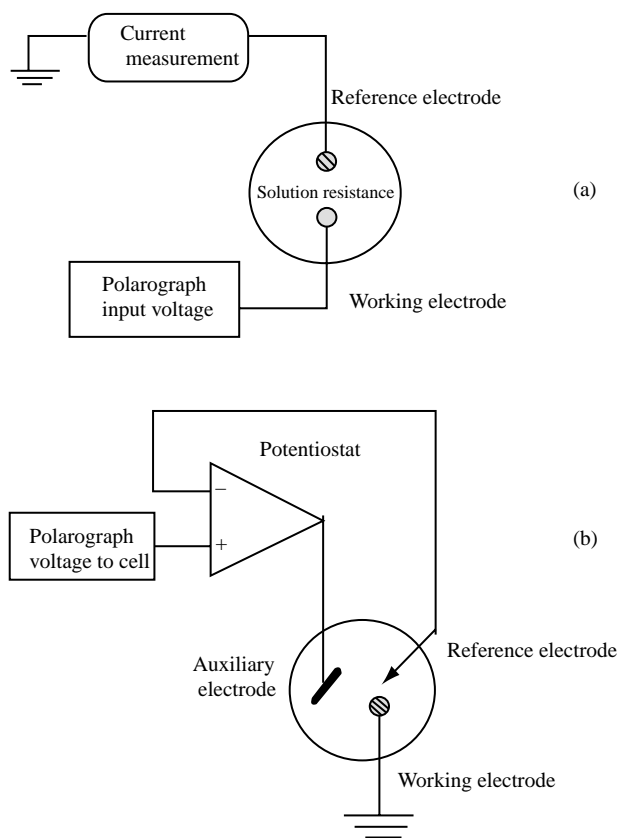

Fig. 5 Electrical circuitry for polarography/voltammetry. (A) A simple two-electrode system. (B) Illustrates a modern three-electrode system incorporating a potentiostat circuit.

elimination of the current variation during the drop lifetime (Fig. 6). However, although the typical serrations of the classic polarogram are gone, a slight staircase pattern can still be discerned on the current-sampled polarogram, a feature shared with many other modern voltammetric methods. The staircase pattern is attributable to the sampled current being held in the memory of the instrument and its value fed out continuously to the recording device until the next sampling period.

Current-sampled polarography offers only a marginal improvement on the sensitivity of the classic method because there is a more favorable faradaic-to-charging-current ratio at the end of the drop time when the drop is almost stationary. Thus, its only real benefit over the classic method is the clearer polarogram obtained.

Pulse Polarography

For routine quantitative analysis, pulse polarography and voltammetry are perhaps the most useful of the modern

Fig. 6 A typical current-sampled polarogram. Note the staircase pattern indicating the individual current sampling periods.

variants on the classic method. Unlike d.c. and current-sampled polarography, the applied voltage is not a simple d.c. ramp but has a more complex format involving periodic application of the potential during short time intervals. There are two major pulse methods: normal (integral) pulse and differential pulse polarography/voltammetry, although many variations of these are now available.

The primary advantage of pulse methods is its significantly more favorable faradaic-to-charging-current ratio and, in the case of differential pulse methods, a more conventional Gaussian-shaped waveform for the current potential plot. In pulse methods, the initial charging current is increased when the pulse is applied, effectively giving a pulse charging current. If the pulse falls on the rising (faradaic) portion of the polarogram/voltammogram, there will be a large increase in current, over and above the value of the pulse charging current. Provided the pulse has been applied at the end of the drop lifetime, when the drop surface area of the DME is briefly constant, or if a solid electrode is used, then both currents will decay from the point of the initial pulse application, the current decay being a function of time. However, the charging current component of the total measured current decays much more rapidly than does the faradaic component. Thus, if the current is measured (sampled) at the end of the pulse application period, it will consist primarily of the faradaic component, thus yielding a marked sensitivity increase over d.c. methods. Sensitivity is also greater because the boundary diffusion layer at the electrode-solution interface

is narrower than is that when the potential is applied continuously. Therefore, the rate of diffusion of the electroactive species toward the electrode is increased, with a concomitant increase in the diffusion current.

Normal (Integral) Pulse Polarography/Voltammetry (NPP/NPV)

In NPP/NPV (5), the voltage is applied in a series of increasing voltage pulses (Fig. 7) from a baseline voltage selected by the analyst. Between pulses, the baseline voltage is restored. The pulse amplitude increases linearly with time, depending on the conditions set by the operator. The voltage pulse is applied at the end of the drop lifetime in polarography. Although precise timings vary with different instruments, typically the voltage pulse is applied for the last 60 ms of the drop. As with current-sampled polarography, the resulting current is sampled over only the final 20 ms of the drop lifetime, producing a polarogram/voltammogram identical in appearance to that of the current-sampled technique but with a greater current yield. The appearance of the polarogram is perceived to be the primary disadvantage of NPP/NPV because analysts tend to prefer a more conventional Gaussian-shaped graphic output of data, the sigmoidal shape being difficult to quantify.

Differential Pulse Polarography/Voltammetry (DPP/DPV)

DPP and DPV are probably the most analytically useful of all the voltammetric methods. DPP and DPV produce current-potential plots in the typical peak form familiar to,

Fig. 7 Applied voltage waveform for normal pulse polarography.

Fig. 8 Applied voltage waveform for differential pulse polarography.

and readily interpretable by the analyst. DPP and DPV result from a variation in the pattern of the applied voltage.

In DPP/DPV, a small fixed voltage pulse of between 5 and 100 mV is superimposed on a slow linear voltage ramp (Fig. 8). When the ramp voltage coincides with the faradaic process, a faradaic current occurs continuously, along with the charging current. When the small pulse voltage is applied, in addition to the ramp voltage, at a given time, then both a new faradaic and a new charging current will be generated. As with NPP/NPV, the faradaic component decays during the pulse application, which, for polarography, is at the end of the drop lifetime. The charging current owing to the pulse also decays, but much more rapidly than the faradaic component so that if the current is sampled at the end of the pulse application, there is maximum separation between faradaic and charging currents and, thus, maximum sensitivity. In fact, in DPP/DPV the current is sampled twice, typically for 20 ms immediately before application of the pulse and again for the last 20 ms of the pulse application. The differential signal thus recorded results from the small increase in current (di) because of the small increase in the applied voltage pulse (dE). This further reduces the charging current contribution before the pulse and leads to an additional sensitivity increase over NPP/NPV. Effectively, it is the derivative (di/dE) of the classic polarographic wave that is produced (Fig. 13). This quantity, when plotted against the applied potential, yields a peak-shaped output because the change in the faradaic component when the constant voltage pulse is applied reaches a maximum on the steepest part of the polarogram and falls to almost zero in the baseline and plateau regions.

The sensitivity of DPP/DPV exceeds even that of the normal pulse method by approximately a single order of magnitude, being approximately equivalent to that of gas chromatography with F.I.D. (approximately 10^{-8} M). It may, therefore, be used for the determination of drugs in biological matrices. In addition, DPP and DPV have excellent resolving power, being able to differentiate peaks, which are no more than 50 mV apart, owing to different electroactive species in the same solution. Both normal and differential pulse techniques are suitable for use with solid working electrodes such as glassy carbon. The various instrumental timings remain the same, even though the constraint imposed by the variable area of the DME has been removed. The $E_{1/2}$ value is, of course, not discernible from DPP/DPV and is replaced by the near-identical quantity E_p , the peak potential.

The magnitude of the peak current (i_p) in DPP/DPV is given by Eq. 4 (6).

$$i_p = \frac{n^2 F^2}{RT} \cdot E \cdot A \cdot C \cdot \frac{D}{\sqrt{\pi t}} \cdot \frac{\exp(E - E_{1/2} + 0.5 E) \cdot CnF/RT}{\{1 + [\exp(E - E_{1/2} + 0.5 E) \cdot nF/RT]\}^2} \quad (4)$$

where n is the number of electrons transferred in the electrode reaction, F is Faraday's constant, R is the universal gas constant, T is the absolute temperature, DE is the pulse amplitude or modulation, A is the electrode surface area, C is the concentration of the electroactive species, D is the diffusion coefficient of the electroactive species, t is the time elapsed from pulse application to current measurement, E is the ramp potential just before application of the pulse, and $E_{1/2}$ is the half-wave potential.

Equation 4 indicates that a linear relationship exists between peak current in DPP/DPV and peak potential and that the peak current will increase with pulse amplitude. However, the charging current also increases with pulse amplitude so that the value for DE must be chosen to maximize i_p but must not be too large; otherwise, resolution of the peak will be diminished. Typical values for DE are 50 or 100 mV.

Linear Sweep Voltammetry (LSV)

Linear sweep voltammetry involves the application of a rapid voltage scan, 100 mV s^{-1} or higher, to a stationary electrode such as the HMDE or a solid electrode such as glassy carbon. The theoretical treatment is based on the Randles-Sevcik equation (2, 7). At slow scan rates, the magnitude of the concentration gradient across the diffusion layer is governed by the rate of depletion of the electroactive species across this layer. With the fast

scan rates used in LSV, the diffusion layer is narrower, the concentration gradient is consequently larger, and the resulting diffusion current is greater. As the depolarizer is used up by reaction at the electrode surface, the diffusion layer widens as it extends further into the bulk solution, and, unlike the DME, equilibrium conditions are not periodically restored by the stirring effect of the falling drop. Thus, there is a gradual decay in the diffusion current, giving a peak-like appearance to the LSV output (Fig. 9). The rapidly increasing potential in LSV results in nonequilibrium conditions at the electrode surface throughout the period of the voltage scan.

Alternating Current Polarography/Voltammetry (ACP/ACV)

Alternating current polarography and voltammetry encompass a wide range of polarographic and voltammetric modes characterized by a periodic applied voltage waveform, such as a square-wave, pulsed, or saw-tooth pattern. The production of such waveforms may require a voltage function generator in addition to the normal polarograph, although some instruments have the function generator built in and can therefore perform ACP/ACV as a standard technique.

The most common applications of ACP/ACV involve the application of a small-amplitude sinusoidal alternating

potential superimposed onto a ramp voltage. The resulting current is an alternating current, the d.c. component being filtered out by use of a phase-sensitive current detector. This is possible because the faradaic and charging components of the current, respectively, have phase angles of 45 and 90° with reference to the applied sinusoidal potential. The detector rejects the 90° component and measures only the faradaic current.

The applied sinusoidal voltage has a typical amplitude range of ± 50 mV, and the polarogram is a plot of the fundamental harmonic alternating current (a.c.) against the ramp voltage. Because the d.c. current component is filtered out, the current values before and after the rising portion of the d.c. polarogram are close to zero in the a.c. mode, and therefore, the resulting polarogram has a peak shape that approximately follows the rising portion of the d.c. wave. The use of a fast voltage scan, analogous to LSV, is possible with ACV at a solid (stationary) electrode.

The special case of square-wave voltammetry (SWV) is worth noting separately from other alternating current techniques because it is both more rapid and more sensitive than DPP/DPV. In SWV, the applied potential waveform is a staircase with constant step height on which is superimposed an asymmetrical forward and reverse voltage pulse of constant amplitude and very short duration, typically less than 10 ms. Thus, the entire polarogram may be run in about approximately 1 s, with the enhanced sensitivity of the method owing to sampling of the current at the end of both the forward and reverse directions of the pulse.

Stripping Voltammetry

This is an ultrasensitive technique most widely used in the trace determination of metals and, increasingly, for organic compounds, including pharmaceuticals. The outstanding sensitivity of the method is due to an initial preconcentration (accumulation) step that can result in a 1000-fold increase in the available analyte concentration compared with the bulk solution. The most commonly used working electrode design for stripping analysis has a single mercury drop hanging from the electrode tip during the course of the stripping experiment. Such an electrode is the HMDE, although other designs such as the mercury film electrode (MFE), in which the mercury is supported as a thin film on a carbon electrode support (8), and SMDE have become increasingly important (9). The SMDE allows faster stirring rates during the deposition step than are possible with the HMDE, the limiting factor in the latter case being the dislodgement of the mercury drop by vigorous stirring. In addition to mercury, nonplated solid

Fig. 9 Typical appearance of a linear sweep voltammogram at a fast-scan rate of 100 mV s^{-1} .

electrodes fabricated from a noble metal (gold or platinum) or from carbon (glassy carbon, carbon paste) have also been used for stripping analysis, typically for the determination of metals that are insoluble in mercury that have very positive redox potentials. For most pharmaceutical applications of stripping analysis that involve organic compounds, mercury electrodes are used. Stripping analysis can then be performed using a conventional modern polarograph linked to a specific working electrode suitable for the chosen analysis.

Stripping analysis for compounds of pharmaceutical interest consists of two steps. First, the electroactive material is deposited onto a mercury electrode, thus concentrating the analate by extracting it from the bulk solution. This controlled deposition, which may be electrolytic, is carried out for a defined time period, with constant stirring of the bulk solution because, in this case, it is necessary to drive the analyte toward the electrode surface as efficiently as possible. Second, there is the stripping step. This involves stripping (removing) the analyte from the electrode surface back into the solution by application of a suitable potential. This second step is the measurement step, the resulting faradaic current being quantitative in respect to the amount of analate present in the bulk solution. The applied potential can be a simple ramp voltage, pulse, or periodic waveform. Thus, most of the modern polarographic modes can be coupled to the stripping step to give additional increases in both sensitivity and selectivity. Fast stripping steps such as the use of the semidifferential mode (10) have become increasingly popular, although differential pulse and linear sweep modes remain prevalent.

Anodic stripping voltammetry (ASV) has been the most widely used stripping variant, typically for the trace analysis of metals in solution. Thus, an electrolytic deposition step onto a mercury cathode, possibly lasting several minutes, is followed by an anodic stripping step in which the potential scan goes toward positive values. The deposition step itself results in the formation of a metal amalgam. As with all stripping variants, hydrodynamic parameters (stirring rate, deposition time, solution composition, electrode location) must be carefully controlled and reproducible to obtain a quantitative response to changing bulk concentrations. The process may be summarized as:

Cathodic stripping voltammetry (CSV) may be considered the reverse of ASV in that the electrolytic

deposition step is carried out at a positive (anodic) applied potential, the deposited analate then being stripped by application of a cathodic voltage scan. CSV has been used for the determination of various anions (11) and for certain drug molecules such as organosulfur compounds (12). CSV may be summarized as:

Adsorptive stripping voltammetry (AdSV) is of increasing importance in trace determinations of pharmaceutical compounds. In this method, the preconcentration step is adsorptive rather than electrolytic, resulting in an adsorbed film of the analate on the electrode surface (13). The stripping step typically uses LSV or the differential pulse mode in either the cathodic or anodic direction, as required. The HMDE is typically used for cathodic reductive stripping, whereas carbon or noble metal electrodes are used in the adsorptive mode.

Factors affecting the adsorptive process in AdSV include the solvent, solution pH, mass-transport processes, stirring rate, deposition time, and applied potential. The sensitivity advantage of AdSV over conventional polarography/voltammetry using an equivalent mode may be up to 100-fold. However, the primary advantage of AdSV is its ability to simplify sample preparation when the analyte is in a complex matrix, such as the determination of a drug or its metabolite in body fluids. Having adsorbed the analyte to the electrode directly from the complex medium, the electrode with the adsorbed analate film may then be transferred to a blank electrolyte solution before the stripping step. This method, known as medium exchange (14), has considerable potential, particularly in a flow analysis mode (15) for both pharmaceutical and clinical analyses. Its value is perhaps not yet fully realized because of a preference for, and greater familiarity with, chromatographic methods.

Electrochemical Detection for High-Performance Liquid Chromatography (ELCD) and Flow-Injection Analysis (ED-FIA)

Pharmaceutical analysts often have no experience in direct polarographic or voltammetric methods, but almost all will have used high-performance liquid chromatography (HPLC) for the determination of drugs and/or metabolites in biological matrices or drugs and/or their degradation products in pharmaceutical formulations. Spectroscopy

(ultraviolet and fluorescence) is the most common detection method in HPLC, but for molecules that do not possess a suitable chromophore or when increased sensitivity or specificity is required, electrochemical detection offers a suitable alternative. ELCD is applicable to any molecular species capable of electrochemical oxidation or reduction at an electrode. Most detectors are based on solid electrodes, notably carbon paste and, particularly, glassy carbon. These detectors are best operated in the anodic mode, but they can also be used for reductive processes. Alternatively, mercury films on a noble metal electrode can be used for cathodic reduction.

The principle of ELCD is described in Fig. 10 and has been addressed in detail by Stulik and Pacakova (16). The detector is set to an applied voltage large enough to cause the electrochemical reaction of interest to occur, i.e., the applied voltage is on the plateau of the polarographic wave. Thus, when the species of interest is eluted from the column, a faradaic current is produced in the detector and results in the usual chromatographic signal. This is an example of amperometric detection because an electrical current is responsible for the analytical signal. With a solid electrode, the detector may be described as a voltammetric detector. Various detector cell designs are available. The most common configuration is the wall-jet cell (Fig. 11), in which the eluent is sprayed against an internal wall of the detector cell. The wall is fabricated from glassy carbon, a highly polished and impermeable material. The flowing eluent spray ensures that any products from the electrochemical oxidation reaction are

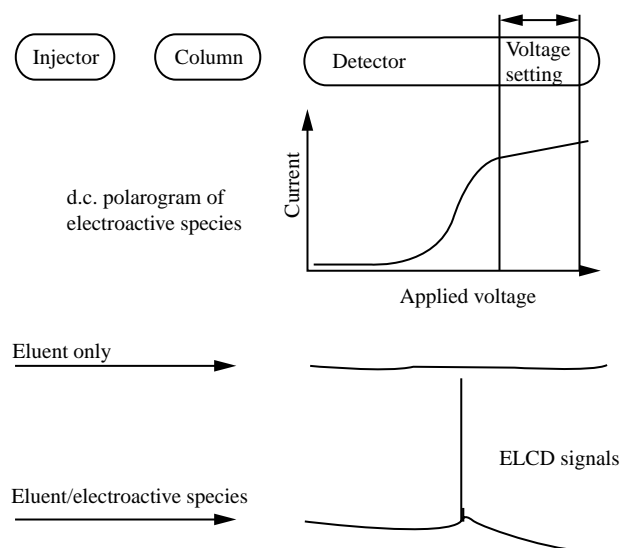

Fig. 10 Principle of electrochemical detection for HPLC.

Fig. 11 Wall-jet electrochemical detector cell for HPLC.

removed from the electrode surface, thus ensuring signal reproducibility.

In conjunction with the various designs of electrochemical detector cells, a range of applied voltage waveforms may be used for ELCD (Fig. 12). The

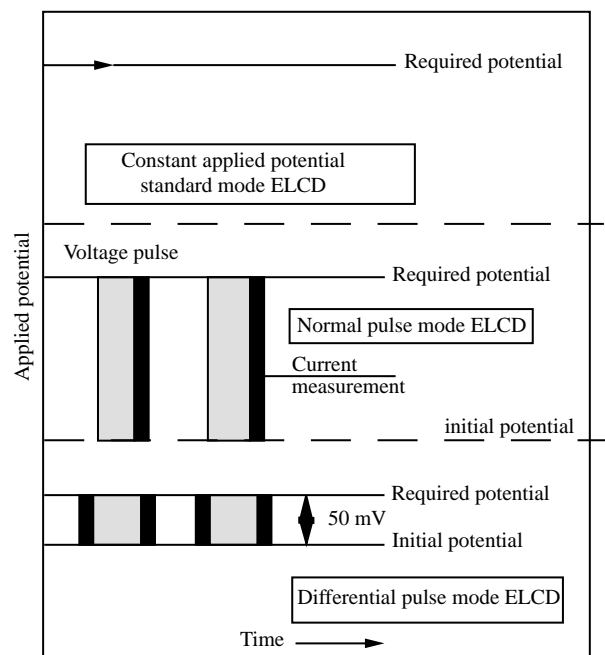

Fig. 12 Applied voltage waveforms for various modes of electrochemical detection in HPLC.

Fig. 13 Differential pulse voltammograms of pyridoxine hydrochloride at the glassy carbon electrode obtained by adding successive aliquots (0.1 ml) of an aqueous solution (0.1M) of the vitamin to pH 4 citric acid as the supporting electrolyte.

differential pulse mode (Fig. 13) is particularly suited to ELCD because it can further enhance the separability of components by selectively setting the detector to the peak potential of an individual component in a mixture.

Additional information can also be obtained using a rapid-scan square-wave detector. As the name implies, this mode uses very fast voltage scans so that a three-dimensional output can be obtained. In effect, many voltammograms are run of a component as it elutes from the column, giving an output of current versus applied potential versus time. Thus, peak purity can be checked, and the device is analogous in its applications to the better known diode array spectrophotometric detector. Voltammetric detectors may also be used in a flow-injection mode (17), effectively omitting the chromatographic step, for drug analysis. Again, a wide range of detector cell designs and polarographic/voltammetric modes are available.

APPLICATIONS OF POLAROGRAPHY AND VOLTAMMETRY TO PHARMACEUTICAL ANALYSIS

A comprehensive review of the use of polarography and voltammetry for drug analysis is beyond the scope of this article. (See Bibliography for reviews on the subject.) The analytical range of the methods is also well illustrated in the references (18–28).

CONCLUSIONS

The availability of a wide range of modern polarographic and voltammetric modes, together with the use of ELCD and stripping analysis, offers the analyst powerful analytical tools for performing drug assays. The decision as to whether an electroanalytical method should be used for a given assay and the selection of a particular polarographic/voltammetric technique will depend on the drug of interest, the analytical matrix, and the type of data that are required. Given the advances in analytical instrumentation, polarography/voltammetry may now be used with confidence, when necessary, by all pharmaceutical analysts.

POLYMORPHISM: PHARMACEUTICAL ASPECTS

Harry G. Brittain

Center for Pharmaceutical Physics, Milford, New Jersey, U.S.A.

INTRODUCTION

It had been known since the middle of the 18th century that many substances could be obtained in more than one crystal form, and so the properties of these solids were studied to the fullest extent possible with the characterization tools (e.g., crystal morphology and melting phenomena) available at that time (1). Eventually the work of von Laue and Bragg on the diffraction of X-rays by crystalline solids led to the development of technology that could be used to directly study the structures of such materials and to provide the structural justification for the phenomenon that became known as polymorphism.

Among other things, it became established that the nature of the structure adopted by a given compound on crystallization would then exert a profound effect on the solid-state properties of that system. For a given material, the heat capacity, conductivity, volume, density, viscosity, surface tension, diffusivity, crystal hardness, crystal shape and color, refractive index, electrolytic conductivity, melting or sublimation properties, latent heat of fusion, heat of solution, solubility, dissolution rate, enthalpy of transitions, phase diagrams, stability, hygroscopicity, and rates of reactions were all affected by the nature of the crystal structure.

Subsequently, workers in pharmaceutically related fields realized that the solid-state property differences derived from the existence of alternate crystal forms could translate into measurable differences in properties of pharmaceutical importance (2). For instance, it was found that various polymorphs could exhibit different solubilities and dissolution rates, and these differences sometimes led to the existence of nonequivalent bioavailabilities for the different forms. Since then, it has become recognized that an evaluation of the possible polymorphism available to a drug substance must be thoroughly investigated early during the stages of development. In various compilations, it has been reported that polymorphic species are known for most drug substances (3, 4) and that one should be surprised to encounter a compound for which only one structural type can be formed.

THEORETICAL CONCEPTS

The full specification of a polymorphic system is specified by the thermodynamic properties of the phases involved. A solid phase has a uniform structure and composition throughout, is separated by other phases by defined boundaries, and undergoes a phase transition when a particular solid phase becomes unstable under a given set of environmental conditions. The course of these phase changes is dictated by differences in free energy at the transition that are associated with structural or compositional changes. Classical thermodynamics provides a basis for understanding the nature of these transitions.

During a phase transition, the free energy of the system remains continuous, while the entropy, volume, and heat capacity undergo discontinuous changes. Phase transitions are classified as being of the same order as the derivative of the Gibbs free energy that exhibits a discontinuous change at the transition. Gibbs free energy (G) is defined from enthalpy (H) and entropy (S) by

$$\begin{aligned} G &= H - TS \\ &= E + PV - TS \end{aligned}$$

where T is the absolute temperature, P is the pressure, V is the volume, and E is the energy. It can easily be shown that transformations in which a discontinuous change occurs in volume or entropy (i.e., requiring a latent heat of transformation) will belong to the first order, while those involving a discontinuous change in heat capacity, thermal expansivity, or compressibility will belong to the second order.

The classical Clapeyron equation adequately predicts the features of first-order phase transitions, and this has been established for a number of examples of first-order transitions effected by the deliberate variation of temperature or pressure (5). Second- or higher-order transitions are not readily explained by classical thermodynamics. Unlike the case of first-order transitions, where the free-energy surfaces of the two phases intersect sharply at the transition temperatures, it is difficult to visualize the nature of the free-energy

surfaces in second- or higher-order transitions. In second-order transitions, changes in heat capacity as well as compressibility and thermal expansivity can be detected at the transition temperature, complicating the analysis.

Under a given set of environmental conditions, the most stable polymorph will be the one having the lowest free energy ($G'_{\text{metastable}} > G_{\text{stable}}$), and all metastable forms must eventually transform to the most stable form. If some combination of P and T exists so that $G'_{\text{metastable}} = G_{\text{stable}}$, then a reversible phase transition may take place and one terms this situation *enantiotropy*. If however, $G'_{\text{metastable}} > G_{\text{stable}}$ at all values of P and T , then any process that converts the metastable form into the stable form must be irreversible. This situation is termed *monotropy*.

One generally finds, therefore, that absolute values for thermodynamic parameters are less important than are relationships that predict the relative stability of the various phases of a polymorphic system. Although it is possible to calculate such energy differences from considerations of the lattice energies of the different structures (6), most workers instead employ the time-honored empirical rules that have been developed over time (7). For instance, since $G'_{\text{metastable}} > G_{\text{stable}}$, then the vapor pressure of the stable form must be less than the vapor pressure of the metastable form.

A number of empirical rules have been proposed to deduce the relative order of stability of polymorphs and the nature of the process that interconverts these (i.e., enantiotropy vs. monotropy). Among the better known are the *Heat of Transition Rule*, which states that if an endothermic transition is observed at some temperature, it may be assumed that there must be a transition point located at a lower temperature where the two forms bear an enantiotropic relationship. Conversely, if an exothermic transition is noted at some temperature, it may be assumed that there is no transition point located at a lower temperature. This in turn implies that either the two forms bear a monotropic relationship to each other or that the transition temperature is higher than the temperature of the exotherm.

Another empirical rule is the *Heat of Fusion Rule*, which states that if the higher melting form has a lower heat of fusion relative to the lower melting form, then the two forms bear an enantiotropic relationship. Less well obeyed is the *Density Rule*, which states that the most dense form will be the most stable at absolute zero. Strictly speaking, the Density Rule is only properly applied to polymorphs of molecular solids where intramolecular hydrogen bonding is not a significant factor.

STRUCTURAL ASPECTS

An ideal crystal is constructed by the regular spatial repetition of identical structural units. One defines the symmetry properties of crystals in terms of a periodic *lattice*, or a 3D grid of lines connecting points in a given structure. The repetitive motif is termed the *unit cell* (which will typically contain a group of molecules), each of which is located at a lattice point. The unit cell is defined by the magnitude of its projections (a , b , and c) along the crystal axes and the angles between the cell axes (α , β , and γ). The symmetry of a crystal is ultimately summed up in its crystallographic *space group*, which is the entire set of symmetry operations that define the periodic structure of the crystal.

When considering the structures of organic molecules, one finds that different modifications can arise in two main distinguishable ways. Should the molecule be constrained to exist as a rigid grouping of atoms, these may be stacked in different motifs to occupy the points of different lattices. This type of polymorphism is then attributable to packing phenomena and so is termed *packing polymorphism*. On the other hand, if the molecule in question is not rigidly constructed and can exist in distinct conformational states, then it can happen that each of these conformationally distinct modifications may crystallize in its own lattice structure. This latter behavior has been termed *conformational polymorphism* (8).

Packing Polymorphism

During the very first series of studies using single-crystal X-ray crystallography to determine the structures of organic molecules, Robertson reported the structure of resorcinol (1,3-dihydroxybenzene) (9). This crystalline material corresponded to that ordinarily obtained at room temperature, and was later termed the α -form. Shortly thereafter, it was found that the α -form underwent a transformation into a denser crystalline modification (denoted as the β -form) when heated at about 74°C and that the structure of this newer form was completely different (10). The crystal structures of the α - and β -forms (viewed down the c -axis, or (001) crystal plane) are found in Fig. 1.

By its nature, resorcinol is locked into a single conformation, and it is immediately evident from a comparison of the structures in Fig. 1 that each form is characterized by a different motif of hydrogen bonding. In particular, the α -form features a relative open architecture that is maintained by a spiraling array of hydrogen bonding that ascends through the various planes of

Fig. 1 Crystal structures of the α - and β -forms of resorcinol, as viewed down the c -axis (001 plane). (Adapted from Refs. 9 and 10.)

the crystal. In the view illustrated (defined by the ab -plane), the apparent closed tetramic grouping of hydroxyl groups is actually a slice through the ascending spiral. The effect of the thermally induced phase transformation is to collapse the open arrangement of the α -form by a more compact and parallel arrangement of the molecules in the β -form. This structural change causes an increase in crystal density on passing from the α -form (1.278 g/cm³) to the β -form (1.327 g/cm³). In fact, the molecular packing existing in the β -form was described as being more typical of hydrocarbons than of a hydroxylic compound (10).

Conformational Polymorphism

Probucol(4,4'-[(1-methylethylidene)bis(thio)]-bis-[2,6-bis(1,1-dimethylethyl)phenol]) is a cholesterol-lowering drug that has been reported to exist in two forms (11). Form II has been found to exhibit a lower melting point onset relative to Form I, and samples of Form II spontaneously transform to Form I upon long-term storage. The structures of these two polymorphic forms have been reported, and detailed views of the crystal structures are given in Fig. 2.

The conformations of the probucol molecule in the two forms were found to be quite different. In Form II, the CSCSC chain is extended, and the molecular symmetry

approximates C_{2v} . This molecular symmetry is lost in the structure of Form I, where now the torsional angles around the two CS bonds deviate significantly from 180°. Steric crowding of the phenolic groups by the t -butyl groups was evident from deviations from trigonal geometry at two phenolic carbons in both forms. Using a computational model, the authors found that the energy of Form II was 26.4 kJ/mol higher than the energy of Form I, indicating the less symmetrical conformer to be more stable. The crystal density of Form I was found to be approximately 5% higher than that of Form II, indicating that the conformational state of the Probucol molecules in Form I yielded more efficient space filling.

Solvatomorphism

One may define a solvatomorph as a crystalline solid in which solvent molecules have become included in the structure through the existence of positional substitution at positions that are site specific and that are related to other solvent molecules through translational symmetry. Other types of structural solvation exist (12) but will not be discussed here. Since water is such a ubiquitous substance, it is not surprising that the most important type of solvatomorphism involves the incorporation of water into a crystal lattice.

Fig. 2 Crystal structures of Forms I and II of Probucol. (Adapted from Ref. 11.)

Ampicillin (4-thia-1-azobicyclo[3.2.0]heptane-2-carboxylic acid) is an antibacterial agent that has been found to crystallize in one trihydrate and at least two anhydrate forms, and the structures of these have been critically compared (13). The transition temperature for the two forms in the presence of water has been found to be 42°C, where the trihydrate forms when crystallization is conducted below this value, and the anhydrate forms when the crystallization is effected at temperatures exceeding 42°C. Structures for the two solvatomorphs are shown in Fig. 3.

The ampicillin molecule exists as a zwitterion in both forms, with the overall molecular configuration being fairly similar as well. The structural differences induced by the presence of the water molecules in the trihydrate phase are evident in the differing configurations of the respective thiazolidine rings, where more planarity is found for the trihydrate phase than is found for the anhydrate phase. It was deduced that the three water molecules were extensively involved in the hydrogen bonding, and that they were located in a channel that lay parallel to one of the molecular screw axes. The intricate network of hydrogen bonding was invoked to explain the relative difficulty associated with dehydration of the trihydrate phase. Finally, the molecular packing of the two forms was judged to be so completely different that the authors concluded that there would be no way for the trihydrate phase to convert to the anhydrate phase as a pure solid–solid transition.

GENERATION OF POLYMORPHS

It is essential to determine the range of crystalline forms that are accessible to a potential drug substance and to determine which of the various forms will be the one used in products used in pivotal trials. To answer this question, investigators must conduct whatever studies might be required to evaluate the full range of possible polymorphs and solvatomorphs. The situation can be further complicated by the phenomenon of disappearing polymorphs, where metastable crystal forms become impossible to produce once more stable forms are uncovered (14).

Ideally, development programs devise a screening protocol for the discovery and preparation of any and all solid-state forms of chemical entities that may exist. Such protocols do not absolutely exclude the discovery of additional forms at later stages of development (i.e., during scale-up), but such approaches provide a comfort level regarding the level of knowledge and awareness regarding the scope of crystalline forms that may exist. A detailed exposition of the means available for the generation of polymorphs and solvates is available (15).

The first and primary method for production of polymorphs entails slow solvent evaporation of saturated solutions, with the rate of evaporation being adjusted by empirical means. Examples of solvents routinely used for such work are listed in Table 1 together with their boiling

Fig. 3 Crystal structures of the anhydrate (viewed down the *b*-axis) and trihydrate (viewed down the *c*-axis) solvatomorphs of ampicillin. (Adapted from Ref. 13.)

Table 1 Solvents routinely used to isolate compound polymorphs and solvates

Solvent	Boiling point (°C)
Dipolar aprotic	
Dimethyl formamide	153
Acetonitrile	81
Dimethyl sulfoxide	189
<i>N</i> -methyl pyrrolidinone	80
Protic	
Water (various pH values)	100
Methanol	65
Acetic acid	115
Ethanol	78
<i>i</i> -Propanol	82
<i>n</i> -Propanol	97
<i>n</i> -Butanol	118
Lewis acidic	
Dichloromethane	40
Chloroform	61
Lewis basic	
Acetone	56
2-Butanone	80
Tetrahydrofuran	66
Ethyl acetate	77
Methyl butyl ether	56
Aromatic	
Toluene	111
Xylene	140
Pyridine	115
Nonpolar	
Hexane	69
Cyclohexane	81

points. The process of solution-mediated transformation can be considered the result of two separate events, beginning with dissolution of the initial phase, and completing with nucleation and growth of the final, stable phase. If two polymorphs differ in their melting points by 25–50°C, for monotropic polymorphs the lower melting, more soluble, form will be difficult to crystallize. The smaller the difference between the two melting points, the easier can it be to obtain the unstable or metastable forms.

Another commonly used crystallization method involves controlled changes in temperature. Slow cooling of a hot, saturated solution can be effective in producing crystals if the compound is more soluble at higher temperatures, while slow warming can be used if the compound is less soluble at higher temperatures. Sometimes it is preferable to heat the solution to boiling, filter to remove excess solute, then quench cool using an ice bath or even a dry ice-acetone bath.

There are situations where kinetics determines the course of crystallization, and thermodynamics becomes of secondary consideration. For example, Ostwald's Law of Stages states that, "when leaving an unstable state, a system does not seek out the most stable state, rather the nearest metastable state which can be reached with loss of free energy." This form then transforms to the next most soluble form through a process of dissolution and crystallization. For crystals whose formation is dominated by kinetic factors, it is essential to isolate the metastable form from the crystallization solvent by rapid filtration so that subsequent phase transformation would not occur.

During the characterization of solids obtained from solvent crystallization studies, one finds that thermal

treatment may be a means to produce new crystal forms. For instance, when using differential scanning calorimetry as an analysis technique, one can observe an endothermic peak corresponding to a phase transition, followed by a second endothermic peak corresponding to melting. Sometimes there is an exothermic peak between the two endotherms, representing a crystallization step. In these cases it is often possible to prepare the higher melting polymorph by thermal treatment.

In accordance with Ostwald's rule, the cooling of melts of polymorphic substances ordinarily yields the least stable modification, which subsequently rearranges into the stable modification in steps. Since the metastable form will have the lower melting point, it follows that supercooling is necessary to crystallize it from the melt. After melting, the system must be supercooled below the melting point of the metastable form, while at the same time the crystallization of the more stable form or forms must be prevented. Quench cooling a melt can sometimes result in formation of an amorphous solid that on subsequent heating undergoes a glass transition followed by crystallization.

Substances often crystallize containing water or solvent molecules located at specific sites in the crystal lattice, defining new crystalline forms known as solvatomorphs. Since water is a pharmaceutically acceptable solvent, hydrate species are of primary importance to drug development. The variety of hydrates that can exist has been summarized (12). Most solvatomorphs form with an integral number for the solvent/molecule ratio, but this is not always the case.

In the simplest type, water is bound to inorganic cations as part of a coordination complex. This type of water is denoted as water of crystallization and is common for inorganic compounds. For example, nickel sulfate forms a well-defined hexahydrate, where the waters of hydration are bound directly to the Ni(II) ion. Well-defined multiple hydrate species can also form with organic molecules, where the water molecules bridge unit cells in the overall structure. Finally, water molecules can exist in a semispecific manner, lining cavities within the crystal structure. This last hydrate type is often termed a channel hydrate.

Typically, hydrates are obtained by recrystallization from water. For example, trazodone hydrochloride tetrahydrate was prepared by dissolving the anhydrate in hot distilled water, allowing the solution to remain at room temperature overnight, and storing the collected crystals at 75% relative humidity and 25°C until they reached constant weight (16). Hydrates can sometimes be obtained by suspending the anhydrous material in water, a process that is analogous to Ostwald ripening. For instance,

aqueous suspensions of anhydrous metronidazole benzoate are metastable, and storage at temperatures lower than 38°C leads to monohydrate formation accompanied by crystal growth (17). The exposure of an anhydrous powder to high relative humidity often yields the formation of new hydrate forms. For example, the experimental anticholesterol compound SQ-33600 was found to form a multitude of hydrate forms on exposure to various relative humidity environments (18).

METHODS OF CHARACTERIZATION

Once a variety of crystalline solids have been produced using a suitable polymorph protocol, it is very important to characterize these by proper techniques so that the system can become better defined. Fortunately, extensive discussions of the techniques suitable for the characterization of pharmaceutical solids are available (19, 20). The fruits of the most important characterization technique, single-crystal X-ray diffraction, have already been discussed in connection with the phenomenon of polymorphism in an earlier section. Certainly the determination of the crystal structures of all possible polymorphs and solvatomorphs would constitute the ultimate in characterization, especially if one could also conduct spectroscopic and thermal investigations on the same crystals used for the structural determination. This situation is rarely realized, so a series of additional techniques are ordinarily brought into use.

Of all the methods available for the physical characterization of solid materials, it is generally agreed that crystallography, microscopy, thermal analysis, solubility studies, vibrational spectroscopy, and nuclear magnetic resonance are the most useful for characterization of polymorphs and solvates. However, it cannot be overemphasized that the defining criterion for the existence of polymorphic types must always be a nonequivalence of crystal structures. For compounds of pharmaceutical interest, this ordinarily implies that a nonequivalent X-ray powder diffraction pattern is observed for each suspected polymorphic variation. All other methodologies must be considered as sources of supporting and ancillary information, but cannot be taken as definitive proof for the existence of polymorphism by themselves.

A correctly prepared sample of a powdered solid will present an entirely random selection of all possible crystal faces at the powder interface, and the diffraction off this surface provides information on all possible atomic spacings in the crystal lattice (21). The relationship between observed scattering angles and the spacings

between planes of molecules in the lattice consists of Bragg's Law:

$$n\lambda = 2d \sin \theta$$

where n is the order of the diffraction line, λ is the wavelength of the incident X-ray beam, d is the distance between the planes in the crystal, and θ is the observed angle of beam diffraction. To measure a powder pattern, a randomly oriented sample is prepared so as to expose all the planes of a sample, irradiated with monochromatic X-ray radiation, and the angles measured at which coherent scattering of X-rays is observed.

An extremely important tool for the characterization of polymorphs and solvates is that of microscopy, since the observable habits of differing crystal structures must necessarily be different and therefore useful for the characterization of such systems (22). Clearly, visual observation of materials suspected of being polymorphs or solvatomorphs would immediately follow their crystallographic study, which in turn would make the science of optical crystallography (23) an essential aspect of any program of study. Both optical and electron microscopies have found widespread use for the characterization of polymorphs and solvates. Although optical microscopy is more limited in the range of magnification suitable for routine work (working beyond 600 \times being difficult when observing microcrystalline materials), the use of polarizing optics introduces enormous power into the technique not available with other methods. Electron microscopy work can be performed at extraordinarily high magnification levels (up to 90,000 \times on most units), and the images that can be obtained contain a considerable degree of 3D information.

Often referred to as fusion microscopy or hot-stage microscopy, thermal microscopy can be an extremely valuable tool for the characterization of polymorphic or solvate systems. The technique requires that one make observations during the heating and cooling of a few milligrams of substance on a microscope slide, as well as observations on the crystallized material (24). It is therefore possible to conduct a very rapid analysis using only small quantities of material, and the entire phase diagram of a drug material can be deduced upon the conduct of suitably designed experiments. The most widely used device in the conduct of thermal microscopic studies is the hot state of Kofler, which has facilitated the conduct of an extraordinary number of studies (25).

Thermal analysis methods are defined as those techniques in which a property of the analyte is determined as a function of an externally applied temperature. Regardless of the observable parameter

measured, the usual practice requires that the physical property and the sample temperature are recorded continually and automatically and that the sample temperature is altered at a predetermined rate. Thermal reactions can be endothermic (melting, boiling, sublimation, vaporization, desolvation, solid-solid phase transitions, chemical degradation, etc.) or exothermic (crystallization, oxidative decomposition, etc.) in nature. Such methodology has found widespread use in the pharmaceutical industry for the characterization of compound purity, polymorphism, solvation, degradation, and excipient compatibility (26).

Although a large number of thermal analysis techniques have been developed, the most commonly applied are those of thermogravimetry (TG, the measure of thermally induced weight loss of a material as a function of applied temperature), differential thermal analysis (DTA, the difference in temperature existing between a sample and a reference as a function of temperature), and differential scanning calorimetry (DSC, the difference in heat capacity between the sample and a reference as a function of temperature). The primary applicability of DTA and DSC analysis to the study of polymorphs and solvatomorphs has been to obtain information about any phase transformations that take place as a function of temperature.

The simplest and most straightforward application of thermal analysis is concerned with studies of the relative stability of polymorphic forms. For example, DTA thermograms enabled the deduction that one commercially available form of chloroquine diphosphate was phase pure, while another consisted of a mixture of two polymorphs (27). DTA analysis was used to demonstrate that in spite of the fact that different crystal habits of sulfamethazine could be obtained, these in fact consisted of the same anhydrous polymorph (28). In a study aimed at profiling the dissolution behavior of the three polymorphs and five solvates of spironlactone, DTA analysis was used in conjunction with powder X-ray diffraction to establish the character of the various materials (29).

DSC analysis can also be used to obtain temperatures of compound melting, and such information can be of value in establishing the relative orders of stability in polymorphic systems. In addition, for suitable systems the technique can be used to study any phase interconversion that takes place during the DSC study. For instance, Form I of iopanoic acid yielded a single melting endotherm at 154°C, but the thermogram obtained on Form II was much more complicated (30). Form II was found to exhibit one endotherm at 133°C (the melting transition of Form I), an exotherm at 141°C (crystallization to Form II), and another endotherm at 153°C (melting of the recrystallized Form II).

DSC analysis represents a superior method of thermal analysis, in that the area under a DSC peak is directly proportional to the heat absorbed or evolved by the thermal event, and integration of these peak areas yields the enthalpy of reaction (in units of calories/gram or Joules/gram). Even though conclusions reached on the basis of enthalpies of fusion are possibly compromised by their omission of the entropy contribution, an indication of the thermodynamic trends inherent in the system is often possible. For instance, the same polymorphic form of moricizine hydrochloride was deduced on the basis of thermal analysis and equilibrium solubility measurements (31). On the other hand, auranofin represents a compound for which one anhydrous polymorphic form is predicted to be the most stable by virtue of its melting point and heat of fusion but for which solubility measurements demonstrate that the other polymorph was in fact the thermodynamically stable form (32).

The energies associated with the vibrational modes of a chemical compound can be observed directly through their absorbance in the infrared region of the spectrum or through the observation of the low-energy scattered bands that accompany the passage of an intense beam of light through the sample (the Raman effect). When the vibrational modes associated with the molecules in a polymorphic system are perturbed by features of the different crystal structures, these methods can be used in the spectroscopic investigation of polymorphs and solvates (33).

When the FTIR spectra of polymorph systems differ substantially, the results may readily permit the identification of a particular form. For instance, the two forms of ranitidine hydrochloride yielded spectra that differed in the region above 3000 cm^{-1} and in the regions spanning $2300\text{--}2700\text{ cm}^{-1}$ and $1570\text{--}1620\text{ cm}^{-1}$ (34). Zanolone has been found to crystallize in a number of different forms, each of which yields a characteristic infrared spectrum (35). When solvent molecules are incorporated in a crystal lattice, the new structure is often sufficiently different from that of the anhydrous phase so that many of the molecular vibrational modes are altered.

The vibrational modes of a compound may also be studied using Raman spectroscopy, where one measures the inelastic scattering of radiation by a nonabsorbing medium (36). Although both infrared absorption and Raman scattering yield information on the energies of the same vibrational bands, the different selection rules governing the band intensities for each type of spectroscopy can be exploited by the skillful worker. For instance, both types of vibrational spectroscopy were used to investigate the polymorphism of nimodipine, and it was evident from the intensity relations that, although each

technique yielded a summary of the vibrational transitions, substantial differences in band intensity were readily discernible (37).

One technique that is becoming increasingly important for the characterization of materials is that of solid-state nuclear magnetic resonance (NMR) spectroscopy, and the application of this methodology to topics of pharmaceutical interest has been amply demonstrated (33, 38). The NMR spectra of polymorphs or solvatomorphs often contains nonequivalent resonance peaks for analogous nuclei since the intimate details of the molecular environments associated with differing crystal structures can lead to perturbations in nuclear resonance energies.

In its simplest application, solid-state NMR spectra can be used to qualitatively differentiate between polymorphs or solvates, much in the manner described for vibrational spectroscopy. When detailed assignments of solid-state spectra have been made, the technique can be used to deduce differences in molecular conformation, which cause crystallographic variations to exist. During the development of fosinopril sodium, a crystal structure was solved for the most stable phase, but no such structure could be obtained for its metastable phase (39). Studies of the solid-state vibrational and NMR spectroscopies permitted the deduction that the solid-state polymorphism was associated with different conformations of an acetal sidechain. The NMR data also suggested that additional conformational differences between the two polymorphs were associated with *cis-trans* isomerization along the peptide bond, which in turn resulted in the presence of non-equivalent molecules existing in the unit cell.

The solid-state NMR technique can be used to deduce quantitative measurements of phase composition, as has been reported for the anhydrate and dihydrate phases of carbamazepine (40). The applications of solid-state ^{13}C -NMR spectra for the study of polymorphs and solvates can go beyond evaluations of resonance band positions, making use of additional spectral characteristics. For instance, studies of $T_{1\rho}$ relaxation times of furosemide polymorphs were used to show the presence of more molecular mobility and disorder in Form II, while the structure of Form I was judged to be more rigid and uniformly ordered (41).

POLYMORPHISM AND SOLUBILITY

Since the different lattice energies (and entropies) associated with different polymorphs or solvatomorphs give rise to measurable differences in a large variety of physical properties, it is hardly surprising that a family of

different forms should exhibit different solubilities and dissolution rates (42). These varying solubilities can in turn be very important during the processing of drug substances into drug products (43) and may have implications for the adsorption of the active drug from its dosage form (44). A solid having a higher lattice free energy (i.e., a less stable polymorph) will tend to dissolve faster, since the release of a higher amount of stored lattice free energy will increase the solubility and hence the driving force for dissolution. At the same time, each species would liberate (or consume) the same amount of solvation energy, since all dissolved species (of the same chemical identity) must be thermodynamically equivalent. The varying dissolution rates possible for different structures of the same drug entity can in turn lead to varying degrees of bioavailability for different polymorphs or solvates.

Solubility determinations were used to characterize the polymorphism of 3-(((3-(2-(7-chloro-2-quinolinyl)-(E)-ethenyl)-phenyl)-((3-dimethylamino-3-oxopropyl)-thio)-methyl)-thio)-propanoic acid (45). The solubility of Form II was found to be higher than that of Form I in both isopropyl alcohol (IPA, solubility ratio equal to 1.7 over the range of 5–55°C) and methyl ethyl ketone (MEK, solubility ratio equal to 1.9 over the range of 5–55°C), indicating that Form I is the thermodynamically stable form over this temperature range. An analysis of the entropy contributions to the free energy of solution from the solubility results implied that the saturated IPA solutions were more disordered than were the corresponding MEK solutions, in turn indicating the existence of stronger solute–solvent interactions in the MEK solution.

Phenylbutazone has been found to be capable of existing in five different polymorphic structures, characterized by different X-ray powder diffraction patterns and melting points (46). While Form I exhibited the highest melting point (suggesting the least energetic structure at the elevated temperature), its equilibrium solubility was the lowest in each of the three solvent systems studied (demonstrating the lowest free energy). These findings indicate that Form I is the thermodynamically most stable polymorph both at room temperature and at the melting point (105°C). Identification of the sequence of stability for the other forms at any particular temperature was not straightforward, and it was concluded that the order of stability at room temperature was not the same as that at 100°C. This clearly indicates that some of the forms are enantiotropically related and that others are related by monotropism.

When the hydrates or solvates of a given compound are stable with respect to phase conversion in a solvent, the equilibrium solubility of these species can be used to

characterize these systems. For instance, the equilibrium solubility of the trihydrate phase of ampicillin at 50°C is approximately 1.3 times that of the more stable anhydrate phase at room temperature (47). However, below the transition temperature of 42°C, the anhydrate phase is more soluble and is therefore less stable.

Solution calorimetry can be used on one level to merely obtain the enthalpy of solution for a given solute, or can be used in a deeper sense to obtain a full thermodynamic description of a system. The determination of solubility data over a defined temperature range can be used to calculate the differential heat of solution of a given polymorphic form. One can subtract the differential heats of solution obtained for the two polymorphs to deduce the heat of transition (ΔH_{Trans}) between the two forms:

$$\Delta H_{\text{Trans}} = \Delta H_{\text{S}}^{\text{B}} - \Delta H_{\text{S}}^{\text{A}}$$

where $\Delta H_{\text{S}}^{\text{A}}$ and $\Delta H_{\text{S}}^{\text{B}}$ denote the differential heats of solution for polymorphs A and B, respectively. The validity of the assumption regarding constancy in the heats of solution for a given substance with respect to temperature can be made by determining the enthalpy of fusion (ΔH_{F}) for the two forms, and then taking the difference between these:

$$\Delta H_{\text{Trans}} = \Delta H_{\text{F}}^{\text{B}} - \Delta H_{\text{F}}^{\text{A}}$$

where ΔH_{Trans} represents the heat of transition between forms A and B at the melting point. When a sufficient number of assumptions are made, one deduces that ΔH_{Trans} and ΔH_{Trans} should be equal, and thus DSC results can be used to verify the solution calorimetry results. For example, the heats of fusion and solution have been reported for the polymorphs of auranofin (32). The similarity of the heats of transition deduced in 95% ethanol (2.90 kcal/mol) and dimethylformamide (2.85 kcal/mol) with the heat of transition calculated at the melting point (3.20 kcal/mol) provides a fair estimation of the thermodynamics associated with this polymorphic system.

To illustrate the importance of free energy changes, consider the solvate system formed by paroxetine hydrochloride, which can exist as a nonhygroscopic hemihydrate or as a hygroscopic anhydrate (48). The heat of transition between these two forms was evaluated both by DSC ($\Delta H_{\text{Trans}} = 0.0$ kJ/mol) and by solution calorimetry ($\Delta H_{\text{Trans}} = 0.1$ kJ/mol), which indicates that both forms are isoenthalpic. However, the free energy of transition (–1.25 kJ/mol) favors conversion of the anhydrate to the hemihydrate, and such phase conversion can be initiated by crystal compression or by seeding techniques. Since the two forms are essentially isoenthalpic, the entropy increase that accompanies the phase

transformation is responsible for the decrease in free energy and may therefore be viewed as the driving force for the transition.

A basic thermodynamic understanding of a polymorphic system requires a determination of the free energy difference between the various forms. The two polymorphs of 3-amino-1-(*m*-trifluoromethylphenyl)-6-methyl-1*H*-pyridazin-4-one have been characterized by a variety of methods, among which solubility studies were used to evaluate the thermodynamics of the transition from Form I to Form II (49). At a temperature of 30°C, the enthalpy change for the phase transformation was determined to be -5.64 kJ/mol. From the solubility ratio of the two polymorphs, the free energy change was then calculated as -3.67 kJ/mol, which implies that the entropy change accompanying the transformation was -6.48 cal/Kmol. In this system, one encounters a phase change that is favored by the enthalpy term but not favored by the entropy term. However, since the overall free energy change (ΔG_{Trans}) is negative, the process takes place spontaneously, provided that the molecules can overcome the activation energy barrier at a significant rate.

In other cases, an unfavorable enthalpy term was found to be compensated by a favorable entropy term, thus rendering negative the free energy change associated with a particular phase transformation. Lamivudine can be obtained in two forms, one of which is a 0.2-hydrate obtained from water or from methanol that contains water and the other of which is nonsolvated and is obtained from many nonaqueous solvents (50). Form II was determined to be thermodynamically favored in the solid state. Solubility studies of both forms as a function of solvent and temperature were used to determine whether entropy of enthalpy was the driving force for solubility. Solution calorimetric data indicated that Form I would be favored in all solvents studied on the basis of enthalpy alone. In higher alcohols and other organic solvents, Form I exhibited a larger entropy of solution than did Form II, compensating for the unfavorable enthalpic factors and yielding an overall negative free energy for the phase change.

It is generally recognized that studies of dissolution rate are best conducted on compacted materials, where the process of forming the compact regulates the particle size and surface area of the solid. Such work yields the intrinsic dissolution rate, the trends of which usually parallel those deduced from studies of equilibrium solubility. Since under constant hydrodynamic conditions the intrinsic dissolution rate is proportional to the solubility of the dissolving solid, the most stable polymorphic form will exhibit the slowest intrinsic dissolution rate.

POTENTIOMETRY

Karel Vytras

University of Pardubice, Pardubice, Czech Republic

INTRODUCTION

Potentiometry is a method of electroanalytical measurement in which the equilibrium voltage of the cell consisting of an indicator electrode and a proper reference electrode is measured using a high-impedance voltmeter, i.e., effective at zero current. The potential of the indicator electrode is a function of particular species present in solutions and their concentration. By judicious choice of electrode material, the selectivity of the response to one of the species can be increased, and thus, interferences from other ions can be minimized. The method allows the determination of concentrations with detection limits of the order of 0.1 μmol per liter, although in some cases, as little as 10 pmol differences in concentration can be measured.

EQUILIBRIA AT INTERFACES

Electric potential is the electric work necessary to transfer the unit charge in vacuum from the infinite distance to a position, the potential of which is to be established. If this position is situated inside of a phase (metal, solution, etc.), it is called the inner electric potential and is denoted by ϕ . The chemical potential of an ion in the presence of an electric potential is called its electrochemical potential, $\tilde{\mu}$, expressed as in Eq. 1:

$$\tilde{\mu} = \mu + zF\phi \quad (1)$$

where μ is the chemical potential, z is the charge of the particle, and F is Faraday's constant ($96.487 \text{ C mol}^{-1}$).

When two phases containing electrically charged particles come into contact, an electrical potential difference develops at their interface. A description of the interface is therefore essential when investigating the charge transfer. If the system is in equilibrium, the appropriate electrochemical potentials must be equal. Thus, for the charged particle i present in phases 1 and 2, Eq. 2 must be valid.

$$\tilde{\mu}_i(1) = \tilde{\mu}_i(2) \quad (2)$$

This equation can be rewritten as in Eq. 3 in terms of the standard chemical potentials, μ_i^0 , and the activities, a_i ,

$$\begin{aligned} \mu_i^0(1) + RT \ln a_i(1) + z_i F \phi(1) \\ = \mu_i^0(2) + RT \ln a_i(2) + z_i F \phi(2) \end{aligned} \quad (3)$$

where R is the gas constant ($8.313 \text{ J K}^{-1} \text{ mol}^{-1}$) and T the absolute temperature (measured in K). Thus, Eq. 4 gives the potential difference at the interface,

$$\begin{aligned} \Delta\phi &= \phi(2) - \phi(1) \\ &= [\mu_i^0(1) - \mu_i^0(2)]/z_i F \\ &\quad + RT/z_i F \ln[a_i(1)/a_i(2)] \end{aligned} \quad (4)$$

which is the so-called Galvani potential difference, $\Delta\phi$.

ELECTRODE POTENTIALS

The potential difference $\Delta\phi$ given by Eq. 4 cannot be measured directly. An electrochemical cell is required, consisting of two electrode compartments (both first and second half-cells). Only in such a cell is the potential difference E measurable, as given by Eq. 5:

$$E = \Delta\phi_{\text{st}} - \Delta\phi_{\text{nd}} \quad (5)$$

If the second half-cell is taken as reference and combined with others, the same value $\Delta\phi_{2\text{nd}}$ occurs in all the differences in Eq. 5. This value can be chosen conventionally and set equal to zero (this amounts to a shift of the coordinate). The electrode for which the condition $\Delta\phi_{2\text{nd}} = 0$ is valid is the standard hydrogen electrode, in which hydrogen under the standard pressure [$p(\text{H}_2) = p^0 = 1.013 \times 10^5 \text{ Pa}$] is bubbled over the surface of the platinum black through a solution of hydrogen ions of unit activity, schematically written as $\text{Pt(s)}|\text{H}_2(\text{g})|\text{H}^+(\text{aq})$, where the vertical lines indicate the interphase. The reaction that determines the electrode potential is the so-called half-cell reaction, $2\text{H}^+(\text{aq}) + 2e = \text{H}_2(\text{g})$. Owing to this convention, the first term of Eq. 5, $\Delta\phi_{1\text{st}}$, can be substituted by E and is called the electrode potential. In the same manner, the first

expression on the right in Eq. 4 can be replaced by Eq. 6:

$$E^0 = [\mu_i^0(1) - \mu_i^0(2)]/z_i F \quad (6)$$

and is called the standard electrode potential (values of selected standard electrode potentials are listed in Table 1).

The simplest situation occurs if a metal (phase 1) is immersed in an electrolyte solution (phase 2), for example, $\text{Zn(s)}|\text{Zn}^{2+}(\text{aq})$. An electrode and its electrolyte make up a half-cell compartment or a so-called first-order electrode, the potential of which is given in Eq. 7:

$$E = E^0(\text{Zn}^{2+}/\text{Zn}) + RT/2F \ln a(\text{Zn}^{2+}) \quad (7)$$

known as the Nernst equation. The expression Zn^{2+}/Zn is used to shorten the half-cell reaction, which is $\text{Zn}^{2+}(\text{aq}) + 2e = \text{Zn(s)}$; a zinc activity in pure zinc solid phase is equal to a unit. It follows from the text above that for a hydrogen electrode, the electrode potential can be written as in Eq. 8:

$$E = RT/2F \ln [a(\text{H}^+)]^2 / p(\text{H}_{2,\text{rel}}) \quad (8)$$

where $p(\text{H}_{2,\text{rel}}) = p(\text{H}_2)/p^0$ is a partial pressure of hydrogen related to the standard pressure, and, in view of the convention, $E^0(\text{H}^+/\text{H}_2) = 0$. Thus, Eq. 8 can be rewritten as Eq. 9:

$$E = -0.05916 \text{ pH} - 0.05916/2 \log p(\text{H}_{2,\text{rel}}) \quad (9)$$

because the term $RT/F \ln 10 = 0.05916 \text{ V}$ at 25°C . Thus, the hydrogen electrode can be considered a pH electrode (analytically, however, it has certain disadvantages compared with the glass electrode that now dominates pH measurements; see below).

Other half-cells that can be used as pH electrodes are metal-metal oxide electrodes. The most widely used is the antimony-antimony oxide electrode, which can be written as $\text{Sb(s)}|\text{Sb}_2\text{O}_3(\text{s})|\text{H}^+$ or $\text{Sb(s)}|\text{Sb}_2\text{O}_3(\text{s})|\text{OH}^-$ and with half-cell reactions assumed to be either $\text{Sb}_2\text{O}_3(\text{s}) + 6\text{H}^+ + 6e = 2\text{Sb(s)} + 3\text{H}_2\text{O}$ or $\text{Sb}_2\text{O}_3(\text{s}) + 3\text{H}_2\text{O} + 6e = 2\text{Sb(s)} + 6\text{OH}^-$. For example, the potential of the electrode can be expressed as Eq. 10, assuming unit activities of Sb, Sb_2O_3 , and H_2O :

$$E = E^0(\text{SbO}/\text{Sb}) - 0.05916 \text{ pH} \quad (10)$$

The electrode is favored for measurements in situations in which other electrodes are easily fouled, but because of its poor precision (0.1 pH unit when properly calibrated), it is mostly used as the pH indicator in titrations. Nevertheless, similar electrodes based on noble metals (for example, $\text{Pd}|\text{PdO}$) are still subjected to further development.

All electrodes depend on oxidation and reduction, but the term oxidation-reduction electrode, or redox electrode, is usually reserved for the case in which a species

exists in solution in two oxidation stages. This electrode is denoted $\text{M(s)}|\text{Ox, Red}$, where M is an inert metal (usually platinum) serving as an electron carrier and making electrical contact with the solution. The half-cell equilibrium can either be simple (e.g., $\text{Fe}^{3+} + e = \text{Fe}^{2+}$) or be affected by other ions (e.g., $\text{MnO}_4^- + 8\text{H}^+ + 5e = \text{Mn}^{2+} + 4\text{H}_2\text{O}$). Corresponding electrode potentials are then expressed by Eq. (11):

$$E = E^0(\text{Fe}^{3+}/\text{Fe}^{2+}) + RT/F \ln a(\text{Fe}^{3+})/a(\text{Fe}^{2+}) \quad (11)$$

or Eq. 12, respectively:

$$E = E^0(\text{MnO}_4^-/\text{Mn}^{2+}) + RT/5F \ln a(\text{MnO}_4^-) \cdot [a(\text{H}^+)]^8 / a(\text{Mn}^{2+}) \quad (12)$$

In the second case, the term of Eq. 13 can be isolated:

$$E^{\text{of}} = E^0(\text{MnO}_4^-/\text{Mn}^{2+}) + 8RT/5F \ln a(\text{H}^+) \quad (13)$$

It expresses the formal redox potential and its pH dependence.

REFERENCE ELECTRODES

An insoluble salt electrode (also called a second-order electrode) consists of a metal covered by a porous layer of its insoluble salt. The whole assembly is immersed in a solution containing a corresponding anion. For example, a silver-silver chloride electrode is denoted $\text{Ag(s)}|\text{AgCl(s)}|\text{Cl}^-$; the electrode potential is a combination of the equation analogous to Eq. 7, and the solubility product of a sparingly soluble salt, $K_s(\text{AgCl}) = a(\text{Ag}^+) \cdot a(\text{Cl}^-)$, is shown in Eq. 14:

$$E = E^0(\text{AgCl}/\text{Ag}) - RT/F \ln a(\text{Cl}^-) \quad (14)$$

where a standard electrode potential for a half-cell reaction $\text{AgCl(s)} + e = \text{Ag(s)} + \text{Cl}^-$ is expressed by Eq. 15:

$$E^0(\text{AgCl}/\text{Ag}) = E^0(\text{Ag}^+/\text{Ag}) + RT/F \ln K_s(\text{AgCl}) \quad (15)$$

In potentiometric measurements, these electrodes are used as reference half-cells. For this purpose, their potential stability must be first guaranteed by the constant anion activity in the solution in contact. The usual arrangement is $\text{metal}|\text{insoluble salt}|\text{inner solution} : \text{test solution}$, where the vertical dashed line marks the diffusive barrier. The most frequently used reference electrodes are the silver-silver chloride electrode (preferred for its stable and reproducible potential, low temperature hysteresis, a wide useful temperature range, and easy preparation; when

s = solid; *l* = liquid; *g* = gas.

filled with saturated KCl solution, its potential is 0.198 V at 25°C) and the calomel (or mercury–mercurous chloride) electrodes (consisting of mercury covered with a paste of Hg and Hg_2Cl_2 , which, when in contact with saturated KCl solution, the potential is 0.244 V at 25°C; a disadvantage of classic calomel electrodes is their considerable temperature hysteresis). Other reference electrodes are not often used.

The Ross reference electrode differs from the others and consists of a platinum wire immersed in a solution containing tri-iodide and iodide ions. The Pt electrode responds to the redox potential established by the iodine(tri-iodide)-iodide couple. This solution is separated from the sample by a bridge electrolyte, which is 3 M KCl.

LIQUID JUNCTION

In a cell with two different electrolyte solutions in contact, as in the application of a reference electrode, there is an additional source of potential difference across the interface of the two miscible electrolytes, inner reference electrode solution : test solution. As noted above, the vertical dashed line is used in a cell scheme to denote such an interface and indicates the source of so-called liquid-junction potential, $\Delta\phi_L$. For example, if two HCl solutions of different concentrations are in such contact, the mobile H^+ ions diffuse into the more dilute solution. The bulkier Cl^- ions follow, but initially more slowly, which results in a potential difference at the junction. However, after the brief initial period, the potential reaches a value that the ions diffuse at the same rate.

Generally, the liquid-junction potential increases with increasing difference of the cation and anion mobilities at the interface. In an ideal situation, both ions are of the same mobility. Such salts are called equitransferent salts, or equitransferent mixtures. For that reason, KCl is commonly used as the inner electrolyte of reference electrodes; a mixture of 1.8 M KCl + 1.8 M KNO_3 serves

best. The liquid-junction potential, although not known, remains constant within limits, appears as a constant offset voltage, and is contained in the apparent (or formal) standard potential, E^{of} . If both H^+ and OH^- do not participate at the border solutions, it usually does not exceed ± 10 mV. In direct potentiometric measurements, the liquid-junction potential can partially be reduced by the use of the reference electrode with a limited diffusion (the boundary between the two miscible electrolytes being a porous diaphragm) or by incorporating a salt bridge filled with a proper electrolyte solution that is equivalent to the use of a reference electrode with two bridge electrolytes (the so-called double-junction reference electrode) containing two porous diaphragms with limited diffusion, e.g., $\text{Ag}(s)|\text{AgCl}(s)|\text{KCl} : \text{a bridge electrolyte} : \text{a test solution}$. In the notation for cells, a double vertical line denotes an interface for which it is assumed that the junction potential has practically been eliminated, e.g., $\text{Ag}(s)|\text{AgCl}(s)|\text{KCl} :: \text{a test solution}$, which is equivalent to the previous scheme.

Some electroanalytical texts that contain sections with emphasis discussed in previous articles are given in Refs. 1 and 2.

MEMBRANE ELECTRODES

The difficulty that can arise with the cells comprising the first- and second-order electrodes noted above is whether oxidized and reduced species of more than one redox couple are present in solution so that they can contribute to the overall equilibrium potential that is thus a mixed potential. Such a measurement can have low selectivity in some real situations. This can be overcome by measuring the difference of potential across a membrane composed from a material that can selectively participate at ionic exchange equilibria.

A membrane separating medium 1 and medium 2 results in a three-phase system, medium 1|membrane|medium 2 because the membrane behaves as isolated phase (M).

Interfaces at which an ionic exchange occurs are geometric barriers between two phases. Membranes for potentiometric electrodes are as immiscible as conveniently possible with respect to the bathing solutions and solid contacts. They are usually constructed of hydrophobic organic liquids and solids or inorganic solids of low water solubility. Nevertheless, useful membranes are not electrical insulators. Porous membranes (organic liquids and solids, synthetic ion exchangers) absorb and become saturated by an external solvent, usually water. They also permit water from two bathing solutions with nonidentical ionic strengths to pass slowly from one side of the membrane to the other. However, many membranes are nonporous, and solvent transport is not an important process when considering membrane potential responses. Useful membranes are often solid or liquid electrolytes because they are composed of partially or completely ionized acids, bases, or salts or contain potentially ionizable species. A characteristic of these membranes is the presence of charged sites. A result of the ionic exchange occurring at both membrane interfaces is the membrane potential $\Delta\phi_M$, expressed as a difference of the inner electric potential of the two phases, which are separated by the membrane, as shown in Eq. 16:

$$\Delta\phi_M = \phi(2) - \phi(1) \quad (16)$$

Generally, the membrane potential is completed by three factors: the two potential differences at both inner and outer interfaces and a liquid-junction potential that can be formed across the membrane (especially in liquid membranes). Nevertheless, a galvanic half-cell, represented by a membrane electrode immersed in the sample test solution, usually consists of an ion-selective membrane, an internal electrolyte, and an internal reference electrode, e.g., $\text{Ag}|\text{AgCl}|\text{internal electrolyte } \text{Cl}^-$, $\text{Q}^+|\text{membrane selective to } \text{Q}^+|\text{test solution}$. This represents a conventional construction of the sensing half-cell; the other half-cell is represented by an external reference electrode. There are many factors to the experimentally observed voltage of a cell containing a membrane electrode that can be considered constant: the inner and outer reference electrode potentials, the potential difference at the inner membrane interface, and, at least in one instant, both liquid-junction potentials formed across the membrane and at the external reference electrode : test solution interface.

Thus, ion-selective membrane electrodes can be defined as electrochemical sensors that allow potentiometric measurements of the activity of particular species in aqueous and mixed solvents or partial pressures of dissolved gases in water. However, these sensors may

respond to certain other ions in the sample in addition to the selected i ion; interferences by such j ions are usually expressed by the Nikolskii-Eisenman (Eq. 17):

$$E = \text{constant} + f(2.303 RT/z_i F) \log\{a_i + \sum k_{ij}^{\text{pot}} a_j^{z_i/z_j}\} \quad (17)$$

where E is the voltage of the potentiometric cell in which an ion-selective membrane electrode participates, and the constant term includes all the constant potential contributions noted above; f is a correction for non-Nernstian response, terms z_i and z_j denote the charge of the ions i and j , and k_{ij}^{pot} is the potentiometric selectivity coefficient.

It should be noted that over the past 30 years, analytical methods utilizing ion-selective technology have been developed at an ever-increasing rate, and much additional information can be found in texts addressing the subject. Some are noted in the references (3–10).

Based on the membrane material, the ion-selective electrodes may be divided into the following groups.

Electrodes with Solid Membranes

These include membranes composed of solid salts that may be single crystals but are more often polycrystalline pellets pressed from powdered starting materials. These solid exchangers respond to species that exchange directly and rapidly and influence the activity of ions that exchange directly. For example, silver salt electrodes are believed to be rapid ion exchangers of both Ag^+ and component anions. In mixtures, Ag_2S holds the more soluble halides in a matrix and produces both electronic and ionic conductivities throughout the membrane. The electrode is also sensitive to other ions that can form sparingly soluble precipitates on the membrane surface, particularly if they have lower solubility products than those of the material of the membrane. As an example, the AgCl -based electrode responds to bromide and iodide; mercury(II) is always a serious interferent because HgS is less soluble than Ag_2S . For the same reason, membranes containing HgS instead of Ag_2S have the advantage of lower detection limits. Some examples of the membrane materials are LaF_3 for fluoride ions, $\text{AgX} + \text{Ag}_2\text{S}$ or $\text{Hg}_2\text{X}_2 + \text{HgS}$ for halide or pseudohalide (CN^- , SCN^-) ions, Ag_2S for both silver and sulfide ions, metal sulfide + Ag_2S for some metal ions (Cd^{2+} , Cu^{2+} , Pb^{2+}), and $\text{Cu}_2\text{Se} + \text{CuSe}$ for copper(II) ions.

Glass Electrodes

These are the oldest and best investigated ion-selective electrodes, made of various multicomponent glasses (11).

The surface of a glass membrane must be hydrated to respond to pH. Hydration is accompanied by a reaction in which singly charged cations of the glass are exchanged for hydrogen ions of the solution $\text{H}^+(\text{aq}) + \text{Na}^+(\text{glass}) = \text{Na}^+(\text{aq}) + \text{H}^+(\text{glass})$. The silicate structure $\text{Si}-\text{O}^-$ of a glass provides cation-bonding sites. A well soaked membrane is covered by a layer of silicic acid gel approximately 10^{-5} to 10^{-4} mm thick.

Glass electrodes respond to the activity of both the hydrogen ion and alkali metal ions in basic solution in which the former is small relative to the latter. At high pH, a negative pH error occurs that suggests that the electrode is responding to alkali metal ions as well as to hydrogen ions. The magnitude of the error varies according to the kind of singly charged cation and the glass composition. Because of this error in early glass electrodes, glasses were developed for which the alkaline error is negligible below a pH level of approximately 12. Other glasses have been developed that allow the determination of cations other than hydrogen ions such as Li^+ , Na^+ , K^+ , and NH_4^+ . Glass electrodes for H^+ , Na^+ , and K^+ are available commercially.

Electrodes with Liquid Membranes

These include membranes made of liquid electroactive substances or with electroactive substances dissolved in a suitable nonvolatile, water-immiscible solvent (mediator). In early designs, the organic phase was placed between two aqueous phases in bulk or with the support of a thin, porous cellulose sheet, sintered glass, or the like. As work with these sensors proceeded, more durable polymer supports were developed, most often poly(vinyl chloride)(PVC). An electroactive compound is dissolved in a solvent (usually tetrahydrofuran or cyclohexanone) together with the PVC and a suitable plasticizer. The solvent evaporates, leaving a plasticized PVC ion-selective membrane. Because the plasticized polymer behaves like a viscous liquid, the properties of the electrode are very similar to those of the original wet membrane. The electroactive materials used in these membranes fall into three main classes: ion exchangers, neutral carriers, and charged carriers.

In liquid ion-exchange electrodes, the electroactive material is usually the salt (ion pair) with a highly lipophilic cation or anion to guarantee oil solubility. For example, nitrate-, fluoroborate-, and perchlorate-selective electrodes are commercially available, based on corresponding ion pairs of an anion with tris(substituted 1,10-Phenanthroline)-metal(II) cations or a quaternary

ammonium salt containing at least one long-chain alkyl group. Selectivity over interferences is limited to ions less oil-soluble than the primary ion. In the case of the above-noted electrodes, the Hofmeister series is usually obeyed:

and can serve as a rule for deciding possible interferences. Similarly, an organic anion such as tetraphenylborate is a suitable membrane counterion for cations (e.g., K^+ , Rb^+ , Cs^+ , Tl^+ , and univalent organic cations). A similar effect is seen because the electrodes are most selective for organic cations such as long-chain quaternary ammonium ions. These cation electrodes have frequently been used as sensors for clinically important molecules that are cationic at low pH levels (drugs).

Another category of liquid-membrane electrodes is based on neutral carriers. These are lipophilic, multi-functional compounds with active groups that are primarily alternating ether and/or keto oxygens that can form a cage for the positively charged ion. Cyclic polyethers and similar macrocyclic compounds, such as valinomycin and nonactin, are believed to discriminate among cations on the basis of size; cations that fit well in the complexing site are most strongly complexed. Potassium-selective electrodes based on valinomycin are the best examples of marketed sensors of this type. Various crown ethers, polyoxyethylene chain-containing compounds, or special selective carriers have been prepared and used in sodium-, barium-, and calcium-selective commercial electrodes.

A third class of ion-selective carriers consists of so-called charged carriers or associated ion exchangers. Unlike the simple ion exchangers, however, the selectivity of charged carriers is dictated by the degree of association of the analyte ion with the carrier as well as the partitioning of the analyte into the membrane solvent. The most notable examples of such agents are the alkyl phosphates originally used in Ca^{2+} -selective electrodes; calcium selectivity is further enhanced by using alkyl phosphonates as membrane mediators.

Gas-Sensing Electrodes

Gas-sensing electrodes are examples of multiple membrane sensors; these contain a gas-permeable membrane separating the test solution from an internal thin electrolyte film in which an ion-selective electrode is immersed. For example, for the ammonia sensor,

the pH of the recipient layer is determined by the Henderson-Hasselbach equation (Eq. 18), derived from the chemical equilibrium between solvated ammonia and ammonium ions:

$$\text{pH} = \text{pK}_a(\text{NH}^+) + \log[\text{NH}_3]/[\text{NH}_4^+] \quad (18)$$

If the solution layer contains a large background concentration of ammonium salt (NH_4^+ picrate is often used), the pH of the immersed glass electrode is proportional to only one variable, $[\text{NH}_3]$, which is in turn dependent on the amount of NH_3 that diffuses across the gas-permeable membrane, as shown by Eq. 19:

$$E = \text{constant} + 0.05916 \log p(\text{NH}_3) \quad (19)$$

where $p(\text{NH}_3)$ is the partial pressure of NH_3 in the sample measured. Similarly, when the glass pH electrode is replaced by a polymeric membrane responsive to NH_4^+ (a nonactin-based NH_4^+ -selective electrode), the signal is not dependent on the pH but on the equilibrium concentration of ammonium acquired from the sample. The ammonia gas-sensing electrode is primarily used for the determination of ammonium salts after the addition of NaOH, which releases ammonia from a sample under test. The total nitrogen can be determined after Kjeldahl decomposition of a sample.

The first gas-sensing electrode based on a similar principle was the carbon dioxide electrode, developed to determine CO_2 in blood. Later, sensors for other gases (e.g., SO_2 , NO_x , and HCN, etc.) appeared on the market.

Electrodes with Biocatalytic Membranes

The gas-sensing configuration described above forms a very useful basic unit for potentiometric measurements of biologically important species (12–17). In principle, the immobilized or insolubilized biocatalyst is placed on a conventional ion-selective electrode used to measure the decrease in the reactants or the increase in products of the biochemical reaction. The biocatalyst include isolated enzymes, subcellular fractions, intact bacterial cells, and whole sections of mammalian or plant tissues. Because ions are usually formed during these reactions, it is possible to determine the substrate by monitoring the ion activity. For example, amygdalin can be degraded by β -Glucosidase to benzaldehyde, glucose, and HCN; the CN^- -selective electrode is used as an inner sensor. Similarly, the NH_4^+ -selective electrode can respond to NH_4^+ ions produced in the reaction of urea with urease.

In recent years, gas-sensing probes have been used most frequently because of their high selectivity over

common cations and anions. Thus, the biocatalytic urea sensor noted above can be constructed by immobilizing urease onto the gas-permeable surface of an ammonia gas sensor; when the probe is inserted into a buffered sample containing urea, the enzyme catalyzes its conversion to NH_3 , which is measured by the gas-sensing electrode described previously. By coupling the efficient and selective catalyzing powers of an enzyme to the selective detection of a gas-sensing electrode, it is possible to construct a sensitive tool for the measurement of many pharmaceutically important compounds. However, in general for biosensors, it should be noted that amperometric principles predominate in a majority of their recent constructions.

SELECTIVITY COEFFICIENTS

In measurements with ion-selective electrodes, interference by other ions is expressed by selectivity coefficients k_{ij}^{pot} , as in Eq. 17. If the nature of the ion-selective membrane is known, these interferences may easily be estimated. For example, in the determination of chloride with a Cl^- -selective electrode containing AgCl as the electroactive component in its membrane, concentrations of bromides or iodides (generally X^-) must be controlled because they form less soluble silver salts than AgCl; the solubility products of corresponding silver halides are used in Eq. 20 to estimate the selectivity coefficient:

$$k_{\text{Cl},\text{X}}^{\text{pot}} \cong K_s(\text{AgCl})/K_s(\text{AgX}) \quad (20)$$

However, this estimation is approximate only. For exact determinations, two methods are primarily used.

In the separate-solution method, the cell voltage E_i is measured first in a solution of free determinant i , followed by E_j measured in a solution of interferant j . By applying Eq. 17 for these two solutions, Eq. 21 is obtained:

$$\log k_{ij}^{\text{pot}} = (E_j - E_i)z_iF/2.303RT + \log a_i - z_i/z_j \log a_j \quad (21)$$

This equation can be simplified further, assuming the main interferants are the ions of the same charge and considering solutions of the same activities.

In the simplest mixed-solution method, the cell voltage is measured in a series of solutions containing a range of activities of the primary ion and fixed activity of the interferant (Fig. 1). When a graph of E versus $\log a_i$ is constructed, the usual Nernstian slope changes

Fig. 1 Calibration graphs of ion-selective electrodes and evaluation of selectivity coefficients. 1) Calibration response against $-\log a_i$ in solution of free determinand i . The practical limit of detection may be taken as the activity (or the concentration) at the point of intersection of the extrapolated lines as shown. 2) Calibration against $-\log a_i$ in the presence of the interferant j , the activity of which is of a known and constant value. Response E_j is obtained for $-\log a_i^* = -\log k_{ij}^{\text{pot}} a_j^{z_i/z_j}$. The resulting interference can restrict the measuring range. b) The abscissa approximately equal to $60/z_i$ mV.

to an invariant E_j voltage at low a_i values, corresponding to the response to a constant a_j activity. The intersection of asymptots to this dependence gives a $\log a_i^*$ value, which is used to calculate k_{ij}^{pot} according to Eq. 22:

$$k_{ij}^{\text{pot}} = a_i^* / a_j^{z_i/z_j} \quad (22)$$

The weakness of all the approaches is the assumption that the slope $2.303RT/z_iF$ is Nernstian or at least unaffected by the presence of interferants. In addition, for many electrodes, especially liquid-membrane systems, selectivity coefficients are not highly reproducible or precise quantities because they are

time-dependent. This is why selectivity coefficients established by various methods can differ; nevertheless, they never differ by order of magnitude, and therefore they serve well to estimate measurement errors in the presence of interfering species.

EQUIPMENT

The selection of equipment for potentiometric measurements is guided primarily by the precision required and the application intended. An instrument must draw essentially no electricity from the cell being used. Historically, measurements (highly precise but tedious) were performed by compensation of the measured voltage with the aid of a reference cell, so that virtually no current passed through the measuring cell. This kind of potentiometer has by now been almost completely displaced by electronic voltmeters with very high internal resistances. This is particularly significant in measurements with membrane electrodes, which may have resistances of 1 to 100 M Ω or even more. These high-resistance instruments are usually called pH meters or ion-meters. A new generation of instruments is represented by microprocessor-controlled meters, making automatic evaluation of the measurements possible. They are produced by many companies (e.g., Orion Research, Radiometer, and Metrohm). Equipment for automated potentiometric titrations has also been developed; the apparatus is generally of the module type, and its individual components (ion-meter, auto-burette, recorder, and computer unit) may be used separately.

EXPERIMENTAL TECHNIQUES

Direct Potentiometry

Direct potentiometric measurements are used to complete chemical analyses of species for which an indicator electrode is available. The technique is simple, requiring only a comparison of the voltage developed by the measuring cell in the test solution with its voltage when immersed in a standard solution of the analyte. If the electrode response is specific for the analyte and independent of the matrix, no preliminary steps are required. In addition, although discontinuous measurements are mainly carried out, direct potentiometry is readily adapted to continuous and automatic monitoring.

Table 2 Standard buffer solutions

Composition	pH Values at °C					
	0	20	25	30	38	60
0.1 m hydrochloric acid	1.187	1.194	1.197	1.200	1.202	1.213
0.05 m potassium tetraoxalate	1.666	1.675	1.679	1.683	1.691	1.723
Saturated (25°C) potassium hydrogen tartrate			3.557	3.552	3.548	3.560
0.05 m potassium dihydrogen citrate	3.863	3.788	3.776	3.766		
0.05 m potassium hydrogen phthalate	4.003	4.002	4.008	4.015	4.030	4.091
1+1 phosphate buffer (0.025 m KH_2PO_4 + 0.025 m Na_2HPO_4)	6.984	6.881	6.865	6.853	6.840	6.836
1+3.5 phosphate buffer (0.008695 m KH_2PO_4 + 0.03043 m Na_2HPO_4)	7.534	7.429	7.413	7.400	7.384	
0.01 m borax	9.464	9.225	9.180	9.139	9.081	8.962
1+1 carbonate buffer (0.025 m NaHCO_3 + 0.025 m Na_2CO_3)	10.317	10.062	10.012	9.966		
Saturated (25°C) calcium hydroxide	13.423	12.627	12.454	12.289	12.043	11.499

Measurement of pH

The electrochemical pH cell consists essentially of a measuring (or indicator) pH electrode, together with a reference electrode, both being in contact with the solution under investigation. Frequently, a pH glass and calomel electrodes are combined; then the pH meter measures the cell voltage E , given by Eq. 23, for example:

$$E = E_{\text{ref}} - E_{\text{ind}} + \Delta\phi \quad (23)$$

where E_{ref} is the reference electrode potential, E_{ind} the indicator electrode potential, and $\Delta\phi_L$ is the liquid-junction potential arising at the boundary between the dissimilar liquids. For a cell with a pH-measuring electrode, Eq. 23 can be rewritten as Eq. 24:

$$E = \text{constant} - 2.303 RT/F \log a(\text{H}^+) + \Delta\phi_L \quad (24)$$

where the constant term (including E_{ref} and the constant substituting E^0 of the pH electrode) and $\Delta\phi_L$ are not available. These unknowns are eliminated by subtracting the voltage $E(X)$ of the cell immersed into a test solution of pH(X) and that of $E(S)$ measured with the same cell immersed into a standard pH(S) solution (Table 2), as in Eq. 25:

$$E(X) - E(S) = -2.303 RT/F [\log a(\text{H}^+)_x - \log a(\text{H}^+)_s] \quad (25)$$

and, subsequently, as in Eq. 26:

$$\text{pH}(X) = [E(X) - E(S)]F/2.303 RT + \text{pH}(S) \quad (26)$$

assuming that the difference $\Delta\phi_L(X) - \Delta\phi_L(S)$ is eliminated. It follows that the accuracy of the pH(X) value is partially dependent on how close in character

the tested solution is to the standardizing solution and how strictly Nernstian the cell response is; clearly, it is desirable to standardize as closely in pH as possible. For more accuracy measurements, it is suggested that two standard buffers be used, pH(S_1) and pH(S_2), which straddle the pH(X) value. The pH(X) is then given by Eq. 27:

$$\begin{aligned} & [\text{pH}(X) - \text{pH}(S)] / [\text{pH}(S) - \text{pH}(S)] \\ & = [E(X) - E(S)] / [E(S) - E(S)] \end{aligned} \quad (27)$$

Eq. 27 represents the so-called practical definition of the pH scale (18). Evidently, in practice the voltage differences expressed in Eqs. 26 and 27 are not measured inasmuch as the meters provide direct pH readings. Hence, instead of the $E(S)$ values, the pH(S) values are adjusted directly on the instrument scale. In the preparation of standard buffer solutions (see Table 2), it is essential to use high-purity materials and carbon dioxide-free freshly distilled water, the specific conductance of which should not exceed 2 $\mu\text{S}/\text{cm}$.

Frequently, it is necessary to measure pH at nonambient temperatures. Biological samples are often stored just above 0°C, clinical samples are measured at 38°C, buffers and gels used in media are measured at approximately 60°C, and many industrial processes take place at higher temperatures. The Nernst equation contains a temperature term that can be corrected by automatic temperature compensation; detailed instructions are attached to each pH meter. The glass Ross pH electrode, containing a Pt wire as a reference immersed in a solution based on iodine (tri-iodide) and potassium iodide, gives the best performance in terms of a fixed, reproducible contact potential that is thermodynamically reversible (the Pt wire potential does change with

temperature, but the redox solution consists of a buffer with an equal and opposite temperature coefficient, which results in a reference system showing almost no potential change with temperature).

Measurement of pX

This includes direct activity (concentration) measurements using other than H^+ -selective electrodes (19). Different methods are available, although none is as well organized as the pH measurement. The simplest procedure is to measure the voltage of the cell containing an ion-selective electrode in solutions of graduated concentrations, usually between 10^{-6} and 10^{-1} mol/L (or similarly on the pH scale, between pX 6 and 1). A typical calibration graph is linear between pX 1 and 5, defined for $pX = -\log a_i$ (Fig. 1). In practice, however, the determination of concentration is more frequently requested. In this case, the cell voltage values are plotted against the logarithms of the concentration of the ion determined, i.e., $pX = -\log c_i$. Such a calibration graph, however, differs from that obtained by measuring the activity at higher concentrations when the activity coefficients y_i are less than 1 (just to remember the relation between activity and concentration, which is $a_i = c_i y_i$). A series of standard solutions with a composition as close as possible to that of the sample is used, and the conditions are maintained identical to those used for the measurement on the sample (pH and ionic strength adjustments, screening of interferants, etc.). The best results are obtained with simulated standards, in which the effects of the other components of the sample solution are included in the calibration curve. As reported recently (20), dramatic improvement of the lower detection limit to phenomenal picomolar concentrations may be obtained by modifying the composition of the inner electrolyte of the ion-selective electrode.

The most frequently used mode (because it is the simplest mode) is calibration with two standard solutions. It is appropriate for any analysis by direct potentiometry in the Nernstian range of an ion-selective electrode, particularly for analyses carried out at varying temperatures. The calibration is performed with two standards in each sample batch. The first gives the value of the cell constant (or E^0 of the sensing electrode) and the second the calibration slope. The two standards should span the concentration range expected in the samples because any error is magnified by extrapolation. In the non-Nernstian region, the concentrations are obtained from a calibration graph rather than by calculation, and because the graph is curved, more (at least four) standard solutions are needed to define it.

Addition (as well as subtraction) methods may also be used. Both require a knowledge of the calibration slope but not of the cell constant. The simplest method includes two voltage readings, E_1 before and E_2 after the addition of a volume V_s of a standard solution to V_x volume of the sample, as shown in Eqs. 28 and 29:

$$E_1 = \text{constant} + \text{slope} \log c_x \quad (28)$$

$$E_2 = \text{constant} + \text{slope} \log (c_x V_x + c_s V_s) / (V_x + V_s) \quad (29)$$

where c_x denotes the concentration of the sample and c_s is the concentration of the standard solution. From the cell voltage change ($\Delta E = E_2 - E_1$), the unknown c_x concentration can be calculated as shown in Eq. 30:

$$c_x = c_s V_s / [(V_x + V_s) 10^{\Delta E / \text{slope}} - V_x] \quad (30)$$

In the well-known addition method, the slope factor is determined simultaneously with the concentration by iterative calculation. If a multiaddition method is used, the unknown c_x concentration can be evaluated graphically (Fig. 2). For $(V_x + V_s) 10^{E/\text{slope}} = 0$, the negative value of the volume equivalent to the unknown concentration is read from an intercept of the dependence with x -axis, $-V_e$, and the concentration calculated as shown in Eq. 31:

$$c_x = -c_s V_e / V_x \quad (31)$$

Flow measurements

A useful and rapid method of automated analysis is the technique of flow-injection analysis (FIA). The sample or a reagent is injected into the stream of a solution of constant composition. Calibration of FIA systems requires the injection of standard solutions, equal in volume to that of the sample, into the carrier stream. The background chemical composition of the standards should be equal, as nearly as possible, to that of the samples. Frequent standardization is not necessary because the measurement of peak height, albeit on a sloping base line, is relatively unaffected by cell voltage drift. Some difficulties can appear with peristaltic pumps, owing to extraneous potentials caused by pulsation of the stream. Cells with a small volume ($<20 \mu\text{l}$) or the cells of the wall-jet type are the most acceptable for continuous measurements (21, 22).

Potentiometric Titrations

In contrast to direct potentiometry, the potentiometric titration technique offers the advantage of high accuracy

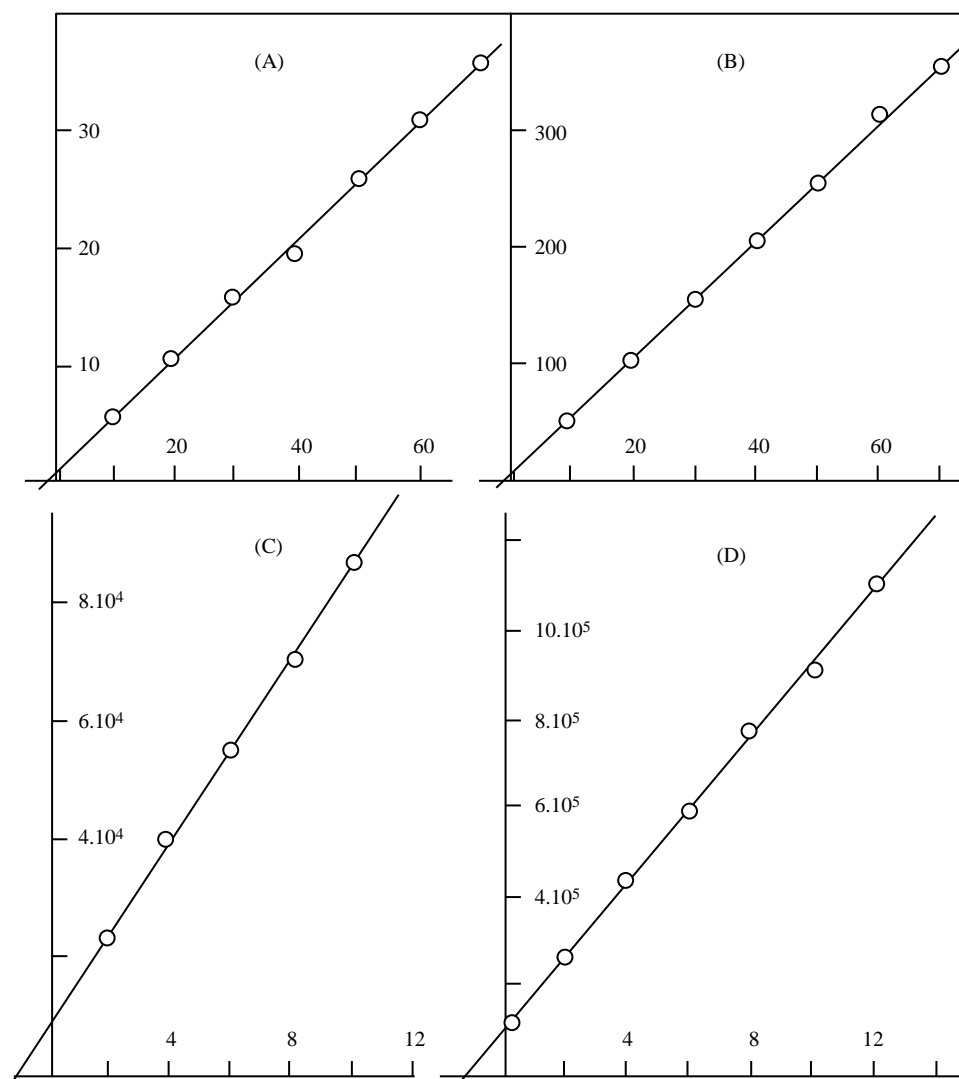

Fig. 2 Multiaddition method with graphic evaluation of the known ion concentration in a sample. Experimental data for the determination of tetrafluoroborate using a BF_4^- -selective electrode. (A) $c_x = 10^{-4}$ mol/L, $c_s = 10^{-2}$ mol/L; (B) $c_x = 10^{-5}$ mol/L, $c_s = 10^{-3}$ mol/L; (C) $c_x = 10^{-3}$ mol/L, $c_s = 10^{-1}$ mol/L; (D) $c_x = 10^{-4}$ mol/L, $c_s = 10^{-2}$ mol/L; $V_x = 100$ mL in all cases. Values of $(V_x + V_s)10^{EF/2.303RT}$ are plotted on the y-axis against volume of the standard solution added, V_s , on x-axis. (Adapted from Sb. Ved. Pr., Vys. Sk. Chemickotechnol. Pardubice **1986**, 49, 149.)

and precision, although at the cost of increased time and increased consumption of titrants. Another advantage is that the potential break at the titration endpoint must be well defined, but the slope of the sensing electrode response need be neither reproducible nor Nernstian, and the actual potential values at the endpoint are of secondary interest. In many cases, this allows for the use of simplified sensors.

For titrations to a fixed potential, the calibration slope is not needed, but the correct potential must be chosen by some means of calibration. In pH titrations, for example,

this can be by means of a buffer solution. The errors involved are usually much smaller than those in direct potentiometry.

PHARMACEUTICAL APPLICATIONS

For analytical control of pharmaceuticals, most pharmacopoeias describe accurate methods, which, however, in some cases are lengthy and difficult. The ion-selective

electrode techniques offer several advantages in terms of simplicity and rapidity over official methods (23–29). Generally, electrodes of all the types noted above can be used to analyze compounds of pharmaceutical significance. For example, halide ion-selective electrodes are often used in the determination of cationic compounds containing quaternary nitrogen and a counter-halide ion. Traditional titration techniques, such as potentiometric pH or redox titrations, are used to determine acids and bases or compounds containing groups that may be oxidized or reduced.

Most ion-selective electrodes, however, cannot be used for the direct determination of functional groups in organic compounds unless they are converted into ionic species. Thus, direct potentiometry is performed rarely with commercial ion-selective electrodes. For example, the CN^- -selective electrode gives an almost Nernstian response in the determination of substituted phenylacetone nitriles and benzonitriles. Thiols can be determined by direct measurement of the voltage of a cell with an Ag_2S -based electrode. Such examples are, however, not typical for applications of ion-selective electrodes.

Typical Drug Substance-Selective Electrode

The typical drug substance-selective electrodes are usually of the liquid-membrane type. It should be noted that virtually any ionic species can be detected and measured by liquid ion-exchange electrodes. The principle for design is as follows: To build a membrane responsive to anion X^- , for example, the salt Q^+X^- is dissolved in a nonvolatile solvent; the Q^+ cation must be highly lipophilic. Similarly, for an electrode responsive to cation Q^+ , an oil-soluble salt Q^+X^- is used, where the X^- anion is lipophilic. Thus, the quaternary long-chain alkyl and aryl ammonium salts and high-molecular-weight cationic dyes etc. are known to behave as liquid anion exchangers suitable for the preparation of anion-selective liquid-membrane electrodes. Tetraphenylborate [or tetrakis(substituted phenyl)borates] and high-molecular anionic surfactants such as dodecylsulfate show good selectivity for heavier univalent inorganic cations and are also often used in membrane electrodes for other “onium” ions. These rules are observed in the construction of drug substance electrodes; a few examples are given in Table 3.

Titration Based on Ion-Pair Formation

In these titrations (28–31), a cationic (Q^+) or anionic (X^-) species is titrated with an oppositely charged

titrant (X^- or Q^+), respectively. If the substance determined or the titrant (or both) has adequate lipophilic character, the poorly soluble ionpair precipitates, $\text{Q}^+ + \text{X}^- = \text{QX}$. Further, the same ion pairs can be used as active substances for liquid membrane-type electrodes because of their good extractability into organic water-immiscible solvents. For that reason, simplified sensors can be used to monitor such titrations. One strategy used with some success is that of coated-wire electrodes. Here, the membrane material is applied directly onto a metal wire (this assembly has no internal reference electrode, which is replaced by a direct contact). In addition, the membranes can be prepared from polymer solutions containing no active material. The organic phase (plasticizer) of a sensor, when immersed in a stirred aqueous suspension of the QX ion pair, becomes gradually saturated, and the concentration is given by Eq. 32:

$$\begin{aligned} [\text{QX}]_{\text{org}} &= K_{\text{ex}}(\text{QX})[\text{Q}^+]_{\text{aq}}[\text{X}^-]_{\text{aq}} \\ &= K_{\text{ex}}(\text{QX})K_{\text{s}}(\text{QX}) \end{aligned} \quad (32)$$

where $K_{\text{ex}}(\text{QX})$ and $K_{\text{s}}(\text{QX})$ are the stoichiometric extraction constant and the solubility product of QX , respectively. The $[\text{QX}]_{\text{org}}$ concentration indicates the number of ion-exchanging places in the membrane, although surface adsorption can also participate. This is why all liquid and/or plastic membrane electrodes sensitive to ions other than those to be determined can also be used to monitor titrations based on ion pair formation. Simple and inexpensive sensors of the coated-wire type, prepared by dipping the central conductor (Pt, carbon rod, but also aluminium wire can be used) into a solution containing dissolved polymer and plasticizer and allowing the solvent to evaporate, are sufficiently suitable.

Regarding titrants, cationic substances (for example, protonized alkaloids, compounds containing quaternary nitrogen, etc.) are usually titrated with sodium tetraphenylborate, the exact concentration of which is determined titrimetrically against a standard substance such as thallium(I) nitrate or pure copper(II) or nickel(II) salts in the presence of 1,10-Phenanthroline. For titrations of anionics, substituted quaternary ammonium or pyridinium salts are applied (30). The procedures are simple and represent an ecologic alternative to so-called two-phase titrations (32).

Titration Based on Complex Formation

Organic molecules containing atoms such as nitrogen, oxygen, and sulfur can donate pairs of electrons.

Table 3 Examples of drug substance-selective electrodes

Substance	Type	Electroactive compound in membrane	Mediator
Acetylcholine	PVC	Acridine orange reineckate	DOP
Amitriptyline	Liq	Eosin, tetraphenyl- or tetrakis(3-Chlorophenyl)-borates as counterions	NC, NT
Amphetamine	Liq	Amphetamine octadecylsulfate	NB
Atropine	Liq or PVC	Ion-pairs of atropine with tetraphenyl- or tetra-kis(3-chlorophenyl)borates, reineckate, dipicrylamine, or tetraiodomercurate(II)	BA, NB, NT, OA or BEHP, DNP, DOP
Bamethan	PVC	Bamethan tetraphenylborate	Various
Brucine	PVC	Potassium tetraphenylborate	DBP
Bupivacaine	PVC	Bupivacaine dinonylnaphthalenesulfonate	
Butylscopolamine	PVC	<i>N</i> -Butylscopolamine tetraphenylborate	DBP
Cholic acid	Liq or PVC	Benzyltrimethylammonium cholate or tributylcetylphosphonium benzoate	NB
Codeine	Liq	Codeine dipicrylamine	NB
	PVC	Potassium tetraphenylborate	DBP
Ephedrine	Liq	Ephedrine 5-Nitrobarbiturate or flavianate	NB or OA
	PVC	Ephedrine tetraphenylborate	DOP
Glutamates	Liq	Methyltricaprylammonium glutamate	DA
Lidocaine	Liq	Lidocaine dipicrylamine or reineckate	NB
	PVC	Tetrakis(3-Chlorophenyl)borate or dinonyl-naphthalenesulfonate as counter ions	DNP or
Nicotine	Liq or PVC	Nicotine tetraphenyl- or tetrakis(3-Chloro-phenyl)borates	NT, NB
Novocaine	Liq	Novocaine tetraphenylborate or dipicrylamine	NB
Oxalate	Liq	Tricaprylmethylammonium oxalate	DA
Papaverine	Liq	Ion-pairs with alkylsulfates, arenesulfonates, or tetraphenylborate	NB
Phencyclidine	PVC	Phencyclidine dinonylnaphthalenesulfonate	DOP
Pilocarpine	PVC	Pilocarpine reineckate or tetraphenylborate	DBP
Quinine	PVC	Quinine tetraphenylborate	DBP, DBS, NB, NPOE
Salicylate	Liq	Tricaprylmethylammonium or tetrahexyl-ammonium salicylate	DA
	PVC	Ethyl violet as a counterion	
	Epoxy	Trioctylmethylammonium salicylate	
Strychnine	Liq	Strychnine picrolonate or tetrakis(3-Methyl-phenyl)borate	
Sulfamerazine	Liq	Tris(bathophenanthroline) iron(II) as a counterion	NB
Vitamins B ₁ , B ₆	Liq	As for papaverine	

Liq = liquid membrane with ion-exchange solution into the porous diaphragm; PVC = plasticized poly(vinyl chloride); Epoxy = conductive epoxy resin membrane. BA = benzyl alcohol; BEHP = bis(2-Ethylhexyl) phthalate; DA = 1-Decanol; DBP = dibutyl phthalate; DBS = dibutyl sebacate; DNP = dinonyl phthalate; DOP = dioctyl phthalate; NB = nitrobenzene; NPOE = 2-Nitrophenyl octyl ether; NT = 2-Nitrotoluene or 4-Nitrotoluene; OA = 1-octanol.

As electron donors, they can form complexes with metal ions (M), which are electron acceptors and are bound as unidentate or multidentate ligands (L). Depending on other groups of the organic molecule, these complexes can be charged or neutral and soluble or insoluble in water. Thus, the chemical reaction can be considered to be $nL + mM = M_mL_n$ (charges are omitted). Experience has shown that the reaction noted above is affected by the pH value and by

competitive side reactions caused by various substances usually present in the solution (such as other ligands from buffer constituents or counterions). Thus, if the conditional stability constant of the complex $\beta(M_mL_n)$ is sufficiently high, the ligand compound can be determined by titration with solutions of metal salts. Appropriate metal ion-selective electrodes are used to monitor these titrations. Regarding pharmaceuticals, many of them can be titrated

with solutions of copper, lead, mercury, silver, and other metal salts (28, 29).

Titration in Nonaqueous Media

Potentiometric measurements in nonaqueous media (33, 34) are performed in a similar manner and with similar apparatus as in aqueous media. There is a difference in the composition of the salt bridge established between the electrode and the solution being tested. In titrations in inert solvents, moreover, there are differences in the shielding and grounding of the titration vessel. Cell voltage is measured using a potentiometer of high internal resistance. Nonaqueous media are used because the substance has low water solubility or it acts as a weak acid or a weak base in aqueous solution. In solvents similar to water, the interactions between solute and solvent resemble the processes that take place in water, but differences owing to the smaller dielectric constants, the formation of different ion pairs by further associations, and the change in the electrostatic field as a function of concentration can be observed. Potentiometric titrations in nonaqueous media can be applied over a wide area; the endpoint varies with the strength of the acid or base to be determined, the solvent, and the titrant. For the determination of water-insoluble weak bases, proton-donating acidic solvents (such as acetic or propionic acids) are used. A titrant is perchloric acid that, dissolved in the medium, gives acetacidium ions $\text{CH}_3\text{COOH}_2^+$. Proton-acceptor basic solvents, such as ethylenediamine, pyridine, butylamine, and dimethylformamide, are used for the solutions of acids and compounds with similar behavior (phenols, imides, sulfonamides, etc.). In this case, the conjugate base of the dissolved acid and the solvated proton are formed; tetrabutyl ammonium hydroxide or other basic titrants are used. In inert solvents such as hexane, benzene, carbon tetrachloride, etc., the highly variable strengths inherent in acids and bases are displayed. The solvent does not take part in the neutralization process, and the product formed is of an additive or associative character.

Titration with Sodium Nitrite

This is a traditional titration that is still often used to determine compounds containing primary amino groups on the aromatic ring, with the endpoint being monitored with a Pt indicator electrode. This method, applied to the determination of pharmaceuticals (sulfonamide-based compounds, benzocaine, procaine, etc.), is rapid, and the results are in good agreement with official methods of analysis (35).

Titration Based on Azo-Coupling Reactions

Aromatic diazonium salts, obtained in titrations with sodium nitrite, can be used in azo-coupling reactions (36). Various aromatic amines, phenols, and compounds containing active methylene groups can be titrated with arenediazonium salts, from which 4-Bromo-1-Naphthalenediazonium chloride seems to be the most widely applicable titrant. Compounds that react slowly with arenediazonium salts can be determined by back-titration when the excess of arenediazonium salt is back-titrated with either sodium tetraphenylborate or 2,4-Diaminotoluene. Indirect determination is useful for secondary amines, which react with arenediazonium ions to form triazenes. The determination of diazonium salts of ampholytic character is based on the reaction of these salts with 1-Phenyl-3-Methyl-5-Pyrazolone, the excess of which is titrated with 4-Bromo-1-naphthalenediazonium chloride solution.

Kinetic Methods

These have also been applied to the analysis of drug substances because they have advantages over equilibrium techniques, especially when mixtures of closely related compounds, compounds that react slowly, or catalytically acting compounds are to be analyzed. The selectivity and sensitivity of kinetic methods of analysis combined with the selectivity and sensitivity of ion-selective electrodes provide a versatile combination that may lead to new analytical schemes (37).

Powder Sampling

Helena J. Venables

Liverpool John Moores University, Liverpool, United Kingdom

INTRODUCTION

Taking a large amount of powder for analysis is expensive and wasteful, and so it must be reduced.

Sampling in its strict sense is therefore a simple mass reduction.^[1]

The purpose is to collect a manageable amount of the powder which is representative of the batch as a whole. Many small samples are taken from all parts of the whole, which, together, are representative.^[2] Theoretically, every particle should have an equal chance to be selected for examination,^[3] and this should be attained with minimum disturbance to the system.^[4] The composition of the original powder must therefore be retained during sampling.^[1] Powder characteristics change under an applied load and attrition and segregation may occur in transfer. Representative sampling is essential for the relevance of any subsequent testing^[2] and is defined by the selection method, which must be accurate and reproducible. To produce reliable samples, a correctly designed sampler is required.^[1] A review of sampling techniques is shown in Table 1.

Important rules should be followed to optimize sampling:

1. Sample from a moving stream of powder.
2. Sample the whole stream for equal periods of time, rather than part of the stream for all of the time.^[2]

OVERVIEW

All analysts have a personal preference for sampling patterns, and random number tables can eliminate this problem.^[6]

Sampling can be undertaken in two ways:

1. By taking increments on flowing streams of powder.
2. By splitting, where the whole is handled.^[1]

The number, the size of each sample, and the method should all be considered. The acceptable error dictates the number of samples to be taken. The more samples taken,

the smaller the error.^[7] Despite extreme care, error causes a difference in composition of a sample from that of the batch.^[8]

It is extraordinarily difficult to carry out any selection process without introducing individual preference or bias into the final selection.^[6]

When determining appropriate sample size, the Scale of Scrutiny must be considered.

SCALE OF SCRUTINY^a

When a mixture is examined closely, regions of segregation are often found. The smallest region that can measure imperfections in a mix is the "Scale of Scrutiny" and can be a length, area, volume, or weight.^[9] The Scale of Scrutiny is directly related to the finished product. If the product is a tablet, then the Scale of Scrutiny is the weight of a tablet. The lower limit is set by particle size.^[10] When the Scale of Scrutiny is large, or when the particle size is small, a large number of particles are present in a sample and the mix appears uniform.^[9] Segregation can never be fully avoided, and sampling the final product is therefore preferred.^[7]

MANUAL SAMPLING^a

Sample Thief

This tool can be useful for free-flowing powders, with two concentric tubes, one enclosing the other. The outer tube is pointed, with holes cut in corresponding positions in inner and outer tubes. The holes are opened or closed through the rotation of the inner tube to capture material (Fig. 1).^[12]

Another variation is a concentric, inner slotted tube with a shoulder at the lower, pointed end. The outer tube has no holes and sits on the shoulder of the inner tube in the closed position. The thief is pushed in the powder diagonally and the outer tube is raised to expose the slot,

which must face upward. The material falls into the container and the tube was removed, slowly opening the tube to collect a representative sample from all parts of the powder bed.^[12]

The thief can sometimes be fairly hard to push into the powder bed, and it is not a good idea to have too many close-fitting, moving surfaces when handling powders, because fines clog and bind between them.^[13] Particles may fracture or fine material may compact by the motion of the sampler, impeding flow. Bias is introduced because of the personal preference for the area sampled. Segregation may occur because of fines percolating into the sample more easily than coarse particles.^[11] A plug of powder can be pushed ahead of the thief and the surface material will contaminate the sample.^[6]

An alternative technique, which reduces segregation, is a unit-dose compacting sample thief (Fig. 2). Bias is still likely with this method because of the invasive nature of any sample thief.^[14]

Hand Scoop

A scoop can take a cross-sectional sample from a bag, barrel, or flowing stream. From the powder stream, a single movement of the scoop completely across the stream collects the sample. Opposite directions for each collection should be used.^[12] The scoop width should be at least 2.5–3 times the largest dimension of the particles to prevent overfilling leading to an excess of fines,^[15] and care must be taken not to leave a thin layer of powder on the belt.^[11] With fines, a larger scoop minimizes moisture

loss, but the volume may be too large and using a shovel would be more convenient.^[15] This method is widely used in manufacturing industries as it is simple and cheap.^[11]

Sampling with a Shovel

In this method, an imaginary grid is applied to a pile of material. At the intersections, pits are dug, roughly 30 cm deep, and a shovelful is taken from the bottoms and sides of each hole.^[12] This method is only applicable to large amounts (up to several tons) of material, but it cannot be used with particles larger than 5 cm in diameter.^[15]

Cross-Cut Sampling

Using a conveyor belt, the belt is stopped and a sample is taken by hand or an automatic or semiautomatic device. A suitable size for sampling can be designated by markings on the conveyor belt and all material within markings was collected. If an automatic system is used, a mechanically operated head moves across the material at a preset interval and moves a sample into the collection point.^[12]

SEMI-AUTOMATIC SAMPLING^a

Pneumatic Lance

This method is used for bulk powder. A gentle flow of air out of the nozzle allows the probe to move through the powder bed. When at the site, air is very slowly reversed

Fig. 1 Sample thieves. (a) Separate holes along the tube, useful for segregation determination. (b) Full length chamber, useful for spot sampling. (c) Chamber at pointed end only to gain an average from many samples.^[11] Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

Fig. 2 The unit-dose compacting sample thief. The sample is collected in the “S” section and the outer rod rotates to open and close the thief. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

to draw up a sample, which is collected against a porous plate at the end of the probe.^[13] The porous plate prevents great numbers of fines being present in the sample if the air current is too strong (Fig. 3). The pneumatic lance minimizes powder disturbance and therefore has an advantage over a sample thief, although bias is still a problem.^[13]

Vacuum Probe Samplers

Large samples can be extracted from bins or holds using a vacuum cleaner principle. Contamination is a problem when sampling below the surface, fines are extracted preferentially to coarse particles, and bias is a problem.^[12]

Gravity-Flow Auger Sampler

A slotted tube is rotated in a flowing mass, and the material collected is carried out of the tube by a worm screw. It is difficult to sample the entire stream, and bias remains to be a problem.^[12]

SAMPLING FROM A MOVING STREAM^a

With these methods, great care should be taken to avoid the effect of segregation. The powder is taken as it falls from the conveyor and can display two types of segregation:

1. If the powder has been charged on the conveyor, fines concentrate at the center of the belt while coarse particles roll to the outer edges such as the segregation seen when sampling from a heap.
2. If the powder is exposed to vibration on the belt, percolation causes larger particles to rise to the top of the powder bed and fines remain at the bottom.

The whole of the powder must be collected for a short period of time, and care must be taken moving the sampler in and out of the stream.^[11]

Various methods exist for sampling from a moving stream and three of these are described (Fig. 4).

Fig. 3 The pneumatic lance. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

With these methods and all others that sample from a moving stream of powder, the dimensions of the sample collector are important. The width of the receiver should be greater for smaller particles than for larger ones because of the tendency for fines to drift during the movement through air. To minimize error, the ratio of box width to particle diameter should be at least 20:1, larger when sampling fines. The depth should be large enough to prevent the receiver from becoming full while sampling. If it overfills, fines will percolate through the heap that forms, while coarse particles are lost. The receiver length should be sufficient to sample the full length of the powder stream.^[11] Disadvantages of this method include:

1. It is difficult and expensive to add to an existing plant but is easily designed into a new one.
2. The sample quantity is proportional to plant rate, which can vary greatly. It can therefore be difficult to obtain a fixed sample, and sample quantity may also be too large.
3. Enclosing the sampler to prevent dust escaping can be difficult.^[11]

Full-Stream Trough Sampler

This can be used for sampling dusty material. Sampling is only carried out on the return stroke (Fig. 5). The trough must not overflow.^[11]

BULK SAMPLING^a

Bag Sampling

When many tons of material need sampling from sacks, several sacks should be selected systematically, i.e., 100th, 200th, 300th, etc. or through use of a random number table or $\sqrt{n}-1$ (9 of 100). Each sample is individually assessed to determine the variation and if it is acceptable, or combined to give an average. The thief sampler is recommended, but this can lead to bias.^[16] It is preferable to use a spinning riffler; however, this is expensive to install. It does avoid rejecting good material and accepting poor material which would occur with the above, inexpensive technique.^[11]

Sampling from Wagons and Containers

This is almost impossible to do satisfactorily because of the major segregation in the filling and vibrations in transport. Sampling should not be carried out in the top 30 cm to avoid the segregation in the surface layer that will have occurred as a result of vibration. When removing the samples, no surfaces on which particles can slide should be introduced. This can be achieved using a sample thief.^[11]

Extraction should be carried out at eight points in the bed (Fig. 6). This method of sampling is not satisfactory but may have to be used in certain circumstances.^[11]

Fig. 4 Methods of sampling from a moving stream. (a) This leads to an excess of coarse particles, if a longer time is taken while stationary than inserting the receiver and removing it, because of the surface usually being rich in coarse particles. This region of the stream is sampled for longer time. (b) This shows good sampling technique. One movement samples the entire stream, but this is not always possible as a result of obstructions. The ratio of stationary time to moving time for the receiver should be as large as possible. (c) This method should be used only when it is not possible to collect the whole of the stream because of too large a sample. A sample collector is passed through the powder stream. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

Fig. 5 The full-stream trough sampler. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

SAMPLING FROM HEAPS^a

This should not be carried out because marked segregation occurs, with fine particles concentrating in the center of the cone (Fig. 7). Powder should preferentially be sampled from a moving stream of powder instead.^[11]

AUTOMATIC SAMPLING^a

A predetermined amount of powder is sampled at regular intervals or continuously. Because of the inherent bias, regular inspections are needed. All the material should be sampled at a constant rate, and clogging of the material should be avoided.

Fig. 6 Locations for sampling from wagons and containers. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

Fig. 7 Segregation in powder heaps. Finer particles are illustrated in black and coarser particles are in white. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

Arc Path Cutter

A chute at an angle is mounted on a vertical shaft, which rotates to periodically move the chute through the stream of powder for a set time. By increasing the speed of rotation, an increase in the number of increments is taken, but this does not alter sample size.

Straight Path Cutters

A rectangular chute moves through the powder stream and rests outside it for a variable time period. This allows different sample sizes to be taken relatively easily. The whole of the stream must be covered to avoid bias.^[15]

Moving-Flap Sample Divider

A flap pivoted about a horizontal axis can rest in either of two positions. The powder stream flows to storage or to be sampled and the time for the flap to be in either position can be controlled automatically (Fig. 8). If the sample is too large, a table sampler is used and an extra powder is returned to the store. This method would be efficient if it was not for the use of the table sampler which causes error.^[11] A slight bias is involved as one side of the stream is sampled more than the other.

Integrated Automatic Sampling Plant

This apparatus selects the primary sample, which is then screened repeatedly to produce the final sample. The method is quick and convenient; however, variations in materials can cause problems and bias in sampling increases as the plant becomes worn.^[15]

SUBSAMPLING^a

This process results in a representative small sample taken from a large one.^[15]

Fig. 8 A moving-flap sample divider. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

Cone and Quartering

Powdered material is poured into a cone and divided into four equal parts. One quarter is recovered and the process was repeated until the required weight of sample is obtained. This method is prone to operator bias, as finer particles tend to remain in the center of the cone because of size segregation.^[17] Symmetry of the cone is also quite difficult to achieve but is necessary for accuracy, so this method is not recommended.^[11]

Chute Splitting

This apparatus is a V-shaped trough, at the bottom of which is a series of chutes feeding two trays on either side

of the trough. The sample enters the chute and is halved repeatedly until the desired sample size is achieved.^[17] The distance between the slots should be at least three times the size of the largest particle diameter.^[15] This method is prone to segregation and operator bias because of the unequal splitting of the sample. It has been found that a greater number of chutes can increase the overall efficiency.^[11]

The Spinning Riffler

A spinning riffler works by running a steady stream of powder into a rotating basket of containers (Fig. 9).^[13] Two or more portions can be collected and it is a continuous dividing process.^[15] The sample of powder contained in each basket can be made more representative by making the baskets rotate faster or increasing the duration of sampling. Rotation speed is limited by air currents disturbing the powder.^[13] Large samples are more difficult to subsample and riffles are very useful in this situation.^[15]

If a powder has good flow properties, then a spinning riffler works very well; however, there should be only a small percentage of fines because air currents displace them and the sample is not representative. The riffler is useful for a single powder ingredient, but segregation can be a disadvantage. It is also fairly expensive and quite time-consuming;^[13] however, the spinning riffler has been found to be more efficient than cone and quartering and the chute splitter and is less prone to operator bias with free flowing powders.^[17]

The efficiency of one riffler was found to be dependent on the relative proportions of the mixture using a mixture of quartz and copper sulfate crystals. Efficiency increased with increasing particle size, was reproducible under similar experimental conditions, and was not affected by the number of volume units (where a volume unit was the

Fig. 9 The spinning riffler. Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

single presentation of a sample to the feed. The minimum was 100 in this experiment set, so this applies only to larger values). These conclusions may not apply where size segregation occurs.^[11]

In another set of experiments, the relative efficiencies of different samplers were compared, and it was concluded that very little confidence could be placed in cone and quartering, scoop sampling, or table sampling. The spinning riffler emerged as so superior to the others that it should be used as often as possible. With the riffler, a minimum of 35 presentations are needed for optimum results to be obtained, and if the speed of rotation is too great, the efficiency falls as a result of air currents setup.^[18]

Free-Fall Tumbling Mixer

This can be used if fines are present in a sample. A sample container is mounted with a ladle in its lid and after a short period of tumbling, it contains a representative sample of the powder as a result of the chaotic conditions created inside the mixer.^[13]

Hopper Sample Divider

The hopper feed oscillates on a horizontal axis, and the powder falls into two collectors. Only one of the contents is kept. Monitoring the amount of time over each container can control sample size. A large number of increments are needed for accuracy.^[11]

Table Sampling

The material is placed on the top of an inclined plane containing a series of holes. Prisms in the path of the stream fraction the powder: some falls into the holes and is discarded while the rest carries onto the next set of prisms and holes and the process is repeated. The powder that remains at the bottom of the plane is the sample. The initial feed must be uniformly distributed and after each separation must be a complete mix because of the errors occurring. There is a very low accuracy with this technique.^[11]

SAMPLING A SAMPLE^a

Having taken great care to extract a sample from a batch of powder, it is pointless to then take a small amount of this sample for analysis with little care of the technique used. By taking a sample from the bulk equivalent to the Scale of Scrutiny, this can minimize problems associated with powder handling. Analytical chemists tend not to realize that what they analyze is the end product of an intricate sampling plan.^[8]

Table 2 Errors involved in the sampling process

Sample	Bias (%)
Primary	≤ 1000
Secondary	≤ 50
Analysis	0.1–1

Reprinted from Ref. [5] by courtesy of Marcel Dekker, Inc.

They (chemists) are content to be mere mechanics, material grabbers. One wonders how many analysts there are that do not realise that taking the analysis sample from a bottle of pulp is a sampling process whose extraction error may be a magnitude greater than the analytical error.^[19]

Sampling is a stepwise process. Errors involved in the sampling process as a whole are illustrated by Table 2. The whole batch is represented by the first sample, the first by the second sample, and so on until the portion for analysis is produced. This is summarized in two main stages:

1. Primary sampling. This involves all steps outside the analytical laboratory resulting in a laboratory sample.
2. Secondary sampling. This includes all steps carried out within the analytical laboratory.^[8]

In the analytical laboratory, seemingly small issues can have large effects on the accuracy of sample analysis. When weighing a sample:

1. Powder may be left on the tray, but weighing by difference does not solve the problem fully. The powder remaining on the tray will most likely be cohesive fines, leading to bias as a result of exaggerated concentrations of coarse particles analyzed.
2. The powder may be “washed in,” leaving none behind. This is preferable, but the choice of solvent is critical to ensure extraction and delivery.^[20]

BLEND UNIFORMITY: A HISTORY

In 1992, the United States filed a court action against Barr Laboratories Inc. alleging that they had violated the Federal Food, Drug, and Cosmetic Act. Barr Laboratories then brought action against the United States, seeking relief from “ad hoc drug regulations.”^[21] Paracetamol (acetaminophen) and Codeine Phosphate tablets were recalled by the company because of doubts as to their potency.^[22] In judgment, Judge Wolin set new standards for the industry. Consequent discussions throughout the

pharmaceutical industry have led, to date, to the Product Quality Research Institute (PQRI) submitting a recommendation to the Food and Drug Administration (FDA) for new industrial guidelines. The ensuing debate is summarized in the following section.

United States vs. Barr Laboratories (1993)

Judge Wolin stated that end-product testing cannot be used to replace blend uniformity analysis (BUA) as he considered it to be limited. Sample size for BUA in validation and production batches should be up to 3 times the active ingredient dosage size, but could be up to 10 times if large errors could be identified and proven to be responsible for batch failures. In the event of failure, the same sample should be retested rather than a newly taken sample as the latter may disguise poor homogeneity. Resampling should not be used to release failed products, unless USP guidelines (content uniformity and dissolution) are followed or the original sample was prepared improperly. Samples should also be taken from weak or hot spots in the blend to demonstrate sampling as representative. Remixing was considered an invalid process which casts doubt on other passing batches; therefore frequent remixing was unacceptable.^[23]

Reactions to the Ruling

Following the “Barr decision,” the FDA suggested that blend uniformity tests should be more stringent than end-product tests as disorder increases as the process progresses.^[24] In response to the recommended sample size of no greater than three times the dosage size (now commonly referred to as the unit-dose sampling requirement), problems with sampling bias were raised. These lead to frequent batch failures and expense within the industry as results are unrepresentative of the blend uniformity.^[25] The entire sample should be analyzed and a duplicate sample retained in case retesting is required.^[26]

The unit-dose samples taken by four different commercially available thieves were compared, and the composition of the samples was found to vary greatly. One thief appeared to produce representative samples and limited bias, although only a single blend type was used.^[27]

Food and Drug Administration Blend Uniformity Draft Guidance (1999)

This document stated that BUA is not usually needed for more than 50 mg active per dosage form unit or more than 50% w/w active in a dosage form. End-product testing alone will normally suffice in these circumstances because of the large proportion of drug present in the blends. Under these limits, BUA is recommended as a routine test.

A sample size of less than or equal to three times the individual dosage weight is also recommended. If the sample bias is an issue and can be proven, up to 10 times the dosage weight can be collected. Six to ten samples should be obtained from drums or blenders, and the weight of the sample tested should be equivalent to the dosage weight used.^[28]

The response from the PhRMA Statistics Working Group was that sampling a blend with a sample thief can segregate the blend, thereby resulting in a sample that is unrepresentative and can be highly variable. Subsampling should not be recommended as it can be unrepresentative and highly variable. Judge Wolin had assumed that sampling using a thief consistently obtained representative samples throughout a powder bed. This is not the case and therefore, in process testing, is not needed.^[29]

Product Quality Research Institute Response

A Blend Uniformity Working Group (BUWG) workshop was held in September 2000, sponsored by PQRI, with attendants from the FDA, industry, and academia. The overwhelming response was that BUA on every batch was not a value-added test as there has been no statistical correlation between blend uniformity and end-product content uniformity. In preference, extended finished product testing was favored. The most common objection to BUA was limited sampling technology.^[30]

The BUWG called for data from pharmaceutical companies to verify the acceptance criteria stated in the FDA's draft guidance. Computer simulations were used, alongside the acquired data to test the hypothesis “blend uniformity testing in routine manufacture is not predictive of the uniformity of dosage units.”^[31] Using this input alongside the research carried out, a recommendation was drafted to the FDA. It stated that both blenders and Intermediate Bulk Containers (IBCs) should be sampled extensively during BUA to determine “dead spots” in blenders, segregation in IBCs, and sampling error presence. Blend sampling designs should then be developed for each product, including variables such as sample thief design and sample size, to try to minimize error and bias. Stratified sampling should be used. This technique deliberately targets weak spots throughout the blending and compression/filling operation to obtain samples. A minimum of 20 evenly spaced sample points for the dosage units should also be defined. These stringent techniques should reveal otherwise hidden errors occurring during process development and eliminate weighing errors in assay.^[32]

The FDA's Pharmaceutical Science Advisory Committee concluded at its May 8th, 2002 meeting that the PQRI recommendation for stratified sampling could be applied to routine production as well as bioequivalence

and validation batches. The FDA will internally review the PQRI recommendations and send them any concerns or further suggestions. The results will form an FDA guidance on content uniformity.^[32]

CONCLUSION

The Scale of Scrutiny must be carefully considered when sampling as both small and large samples can give very misleading results.

Sampling is integral to analytical techniques at all stages of manufacture especially in scale up. Undertaken correctly, it can prevent the losses that the company may suffer from otherwise. Although it is not revenue-producing, it is important economically and heavy losses can easily be avoided through the use of correct techniques.

Overall analytical reliability depends on sampling accuracy (negligible bias) and reproducibility (acceptable variance).^[8]

Guidelines are to sample from a moving stream of powder and to sample the whole of the stream for many equal periods of time. This ensures that all parts of the powder are equally accessible and this maximizes accuracy.^[2] The sample thief does not meet these criteria and therefore should not be used. Despite being popular, it suffers from many disadvantages, which lead to bias and error. Most other methods are immediately ruled out as suitable if these guidelines are followed.

The automatic sampling methods discussed are subject to bias, sampling some parts of the stream more than others. Sampling directly from a moving stream involves great care to avoid segregation, but method "b" in "Sampling from a Moving Stream" can avoid this problem.

Two important methods are the spinning riffler and the free-fall tumbling mixer. The first has been proven to be the most superior method of sampling in experiments and should be used whenever possible. The second has not been investigated fully but deserves further study. Methods that rely on chaotic conditions created in the mixing process should be perfect for sampling. The powder is in motion and all is sampled, following the recommended guidelines. The problem of losing fines into the surrounding atmosphere is also avoided.^[13]

If the FDA chooses to follow the stratified sampling recommendation of the PQRI, blend uniformity testing and the large problem of sampling may soon become history. Until then, however, guidelines should be followed at all times, awareness should be raised to minimize errors, and the importance of sampling should not be underestimated. Testing must be carried out frequently to ensure that each blend reaches the standards set.

ACKNOWLEDGMENT

I would like to thank my Director of Studies, Dr. James Wells, for all his help with my research. I would also like to thank my sponsors Pfizer Global R&D for their support and Marcel Dekker, Inc. for allowing the reproduction of material.

POWDERS AS DOSAGE FORMS

Jean-Marc Aiache

Erick Beyssac

Faculty of Pharmacy, Clermont-Ferrand, France

INTRODUCTION

Powders are both the simplest dosage forms and the basis of many other solid dosage forms, such as tablets, capsules, etc. Many drugs or ingredients are also in powder form before processing.

Powders were originally designed as a convenient mode of administering hard vegetable drugs such as roots, barks, and woods; powders were also found to be convenient for dispensing insoluble chemicals such as calomel, bismuth salts, mercury, and chalk.

Presentation in powder form permits drugs to be reduced to a very fine state of division, which often enhances their therapeutic activity or their efficacy by an increase of dissolution rate and/or absorption (1, 3–5). Divided powders are also found to be convenient for administering drugs that are excessively bitter, nauseous, or otherwise offensive to the taste.

This article describes the preparation of powders from bulk materials to finished products according to the administration routes, packaging, and storage conditions.

HISTORICAL BACKGROUND

In all the old books of Pharmacy were included powdered dosage forms resulting from the fine division of animal, vegetable, mineral, and synthetic solid substances (1).

Such powders can be administered singly (simple powders) or as a mixture of different medicinal powders (compound powders) (5). One of the most ancient compound powders was “Hiera Picra” (sacred bitters), a mixture of Aloe and Canella introduced in about 500 B.C. as a laxative (3). (A large number of bitter powders containing Aloe as the principal ingredient bore the name of Hiera.) This powder was listed in various Pharmacopoeias, and it was recognized up to the 4th edition of the *National Formulary* (official until 1926).

Other famous compound powders of the past (1–8) include:

- compound powder of Glycyrrhiza
- compound Senna powder

- Dover’s powders introduced by the English physician Thomas Dover as Pulvis Diaphoreticus in the early Eighteenth century (and until recently in some Pharmacopoeias)
- aromatic powder of chalk (a simplified version of a complex confection devised by Sir Walter Raleigh during his imprisonment) known as The CONFECTIO RALEGHIANA (1721)
- Dr. James’ antimonial powder (fever powder) patented in 1747
- SEIDLITZ powders (a saline cathartic originated and patented by Thomas Savory in 1815). They owed their value to the mineral properties of the Seidlitz springs in Germany (which contain magnesium sulfate).

DRUG POWDER FORMULATION

According to the European Pharmacopeia, powders as dosage forms are made of solid, dry, free, and more or less fine particles. They contain one or more active ingredients with or without excipients and if necessary, coloring or flavoring substances.

So, the formulation of powders as dosage forms is performed according to the following steps:

- obtention of powder as raw material from an original drug (animal, vegetable drugs, or animal or synthetic chemical entities) by different methods of division:
- mixing of various powders with or without excipients as a function of the powders’ characteristics (e.g., flow properties)
- modification of their density (e.g., by granulation) if necessary
- packaging of the finished product for an easy patient’s use

OBTENTION OF POWDERS AS RAW MATERIAL

Introduction

The main process is the mechanical (5) division that reduces lump drugs into fragment of different sizes

(coarse division). To reduce the size, comminution is then used.

Coarse division includes various operations such as cutting, chopping, crushing, grinding, milling, micronizing, and trituration, which depend on the type of equipment used, on the raw material to be treated (vegetable, synthetic, or mineral), and on the convenient particle size. These operations produce heat during processing, which makes it necessary to know certain physical and chemical properties of the drug itself, such as:

- liquefaction temperature
- melting point
- sticking properties
- thermolability
- hardness
- moisture content
- brittleness

Some physical aspects of fracture mechanisms are existing: Crushing or comminution produces small-sized particles that present a new free surface area. This requires energy. With current knowledge, it is not possible to determine accurately the necessary energy for good comminution, according to the particle size before and after treatment and their physical properties (e.g., brittle, elastic, viscous, plastic) (9).

Several fundamental laws have been suggested and they have been described previously (10–13).

Methods and Equipment

First, to decrease risks of contamination and deterioration, the equipment used in pharmaceuticals should be made of stainless steel, be easy to disassemble for cleaning, and be used in a closed room equipped with a dust removal system.

Coarse division

The devices are described in Table 1.

Comminution

Comminution gives particles smaller than that coarse division. The following factors may influence the choice of the appropriate device:

Physical properties of the drug (13)

Hardness: Hard substances must be subjected to compression, impact, and abrasion or milling, but equipment wear is severe. In some instances, mill wear may be so extensive that it leads to highly contaminated products.

Abrasiveness: This is measured on Moh's scale: 1–3 = soft substances, 8–10 = hard substances.

Elasticity

Friability

Friability: Plant products require a cutting or a chopping action and cannot be subjected to pressure or impact techniques (9, 10).

Moisture content: Several Pharmacopoeias recommend drying (moisture content < 5%) the drug substances before comminution (oven at 40–45°C) to avoid liquefaction or agglomeration. Hydrates that may release their water during the process require cooling or low-speed processing.

Initial feed particle size and degree of size reduction desired: Each device has a reduction ratio: it can accept materials of sizes in a certain range and will provide particle of a set size. The particle size distribution of the obtained powder must be as even as possible to obviate further treatment of the larger particles. It is therefore useful to combine, in the same equipment, a milling device with some type of classifier, such as a screen. The oversize particles are returned to the mill on a continuous basis while the particles of the desired size pass through the screen. This kind of equipment is very convenient for sensitive substances or to prevent overmilling and overproduction of fines.

Table 1 Different operations of a coarse division (with definition and devices used)

Operation	Definition	Devices used
Cutting	Obtention of coarse fragments (e.g., vegetable drugs)	Blades
Crushing	Division of coarse fragments	Mortar and pestles (Wedgwood ware, porcelain, glass, iron)
Attrition	Breaking down a substance by rubbing two surfaces together	Non-or stainless steel worn

Table 2 Different operations of comminution (with their devices)

Operation	Laboratory scale devices	Industrial scale devices ^a
Attrition	Mortar and pestles	Jaw crushing device
	Grinding stones	Mills (vertical or horizontal)
	Cutter mills	
	Sieves and screens	
Rolling	Roller mills	Roller mills (smooth or saw-toothed cylinders)
		Attrition mills (diameter 1–2 mm)
		Cutter mills (diameter > 0.2 mm)
		Hammer mills (can be used in liquid
		N ₂ or CO ₂ to decrease the milling temperature
		and to protect the drug product)
		Pebble or ball mills (diameter
		< 2 mm)(planetary pot or jarr
		mills or vibration mills)
		Micronizers or jet mills (fluid-energy mills)
		(diameter 1–10 μm)
		Centrifugal impact pulverizer (diameter 0.05–2 mm)

^aAll these devices have been described (see Ref. 13).

Particle shape desired (13): Different kinds of equipment produce different shapes (Table 2).

Quantity of material to be treated: The selected equipment must have the required capacity. The operation can be continuous or not.

All these operations are achieved by sieving to separate the coarse particles for grinding again if necessary.

It is to be noted that safety must be taken into account:

Noise: All equipment must be installed in a special sound-insulated room.

Toxicity: Due to particle air diffusion, protection of workers is compulsory. Cross-contamination must also be prevented.

Powder Characterization

Particle size

All these data must be introduced in the drug product registration file as well as for the raw material due to their impact on the drug bioavailability as for the powder dosage form as finished product.

A powder is characterized by its particle size, which is of importance in achieving optimum production of medicines (9). First of all, this parameter influences the dissolution rate of the drug in vivo, which in turn influences absorption rate and the onset of therapeutic activity. Particle size is important during the production of solid dosage forms in the manufacture of tablets and capsules. Appropriate equipment controls the mass of drug

and other particles by volumetric filling. Any interference with the uniformity of fill volumes may therefore alter the mass of the drug incorporated into the dosage form (tablets or capsules) and so reduce the content uniformity. Powders with different particle sizes have different flow and packing properties, which alter the volume of powders during each event. To avoid such problems, the particle size of drugs should be defined during formulation and must be as uniform as possible (9).

However, it is not easy to evaluate the particle size of a powder. For a large lump, it is possible to measure it in three dimensions. But if the substance is milled, the resulting particles are irregular with different numbers of faces and it would be difficult or impracticable to determine more than a single dimension (14). For this reason, a solid particle is often considered to approximate to a sphere characterized by a diameter. The measurement is thus based on a hypothetical sphere that represents only an approximation to the true shape of the particle. The dimension is thus referred to as the equivalent diameter of the particle (14).

It is possible to generate more than one sphere that is equivalent to a given irregular particle shape. It is useful to evaluate Feret’s or Martin’s statistical diameter (12), which depends on both the orientation and shape of particle. Feret’s diameter is determined from the mean distance between two parallel tangents to the projected particles perimeter, and the Martin’s diameter is the mean chord length of the projected particle perimeter (Fig. 1). Instead of sphere equivalent diameter, it is possible to use equivalent

Fig. 1 Influence of particle orientation on statistical diameters. The change in Feret's diameter is shown by the distances, d_F ; Martin's diameter (d_m) corresponds to the dashed lines.

volume, sedimentation volume, mass, or sieve mass of a given particle to determine the particle size of a powder.

Finally, as powders contain particles of different diameters, it is necessary to present the results of size distribution in the form of histogram corresponding to each equivalent diameter evaluated. Such a histogram presents an interpretation of the particle size distribution, enabling the percentage of particles having a given equivalent diameter to be determined and allowing different particles size to be compared (Fig. 2A). An alternative to the histogram representation is obtained by sequentially adding the percent frequency values (Fig. 2B) to produce a cumulative percent frequency distribution (14). Finally, to summarize the data obtained in determining particle size, it is possible to use statistical methods (14).

Recently, some recommendations to include the following items in a particle sizing validation report have been published (15):

- the procedure (or reference to it)
- precision
- range (suitability assessment including microscopic comparison)
- robustness

Detection limit, quantification limit, accuracy, and specificity are not normally considered appropriate for validation of particle sizing methods.

The author of these recommendations added that the validation of particle sizing technique cannot be completed with the first batch of a sample, as data are insufficient to fully validate the procedure at this stage. It is not always important to know the absolute particle size of the first batch manufactured, but it is important to know how the second and subsequent batches compare with it. The validation of a particle size method should be in phases, with parts completed when the first sample is analyzed and

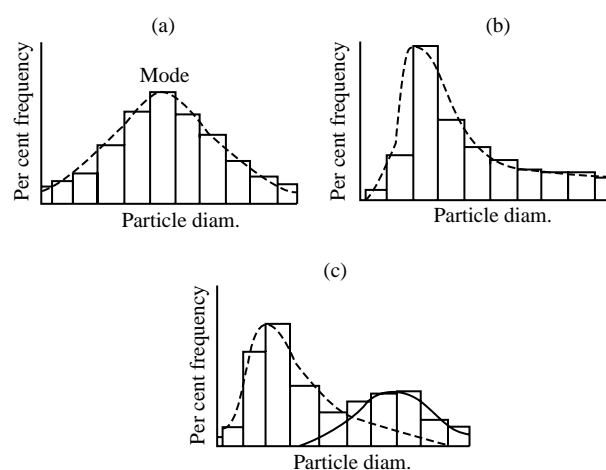

Fig. 2 Frequency distribution curves corresponding to (A) a normal distribution, (B) a positively skewed distribution, and (C) a bimodal distribution.

other data completed or added later, for example, prior to the regulatory filing. Calibration or verification of an instrument being used is assumed to be normal part of GMP and may be used as a suitability assessment (15).

The different methods of particle size analysis can be grouped into several categories: size range analyses (sieve methods), wet or dry methods, and manual or automatic methods (laser-light). All these methods are described elsewhere (16, 17).

Flow properties (18, 19)

Flow properties of powders are important parameters in mixing and segregation phenomena, essentially during storage.

Depending on manufacturing and packaging processes, different flow characteristics are required that are essential for quality control and for the optimization formulation.

In fact a powder, as it has been said, can be made of one or many active powder drugs with or without excipients, and this final mixture will represent the dosage form to be packed and dispensed to patients. So, it is necessary in most of the cases to add excipients for diluting the active powder drug, to improve the packaging properties, and/or to insure a good compliance from the patient (e.g., taste masking). So, the excipients must present the following properties:

- optimal particle size distribution
- high flowability
- high compressibility
- optimal capacity for a drug

- sufficient reworkability
- physiologically inert
- resistant to heat, humidity, and oxidation
- tasteless and odorless

The bulk mixture obtained must present flow properties that are determined by

1. flow through an orifice
2. angle of repose
3. bulk density or bulk tapped density (18)
4. shear cells

These methods are described quite in all the pharmacopeias and in an article elsewhere (20).

OBTENTION OF POWDERS AS DOSAGE FORMS

A powder as dosage form, as it has been said, is made of one or more drug powders, generally, with excipients. So, the mixing of all the components and the validation of this operation are very important.

Mixing of Powders

The aim of mixing is to obtain a homogeneous association of several solid products. Each fraction or dose randomly sampled must contain all the components in the same proportion as in the whole preparation (21). This is achieved because the different components “are treated so as to lie as nearly as possible in contact with a particle of each of the other components” (22).

Mixing has been described as a stochastic process by means of stationary and nonstationary MARKOV chains (10) in which the probabilities of particle movement from place to place in the bed are determined.

To obtain a good mixture, it is necessary to take into account the characteristics of the raw material, the finished mixture, the equipment used, and the operating conditions. The mixing process must be validated (discussed later).

Factors influencing the mixing of powders

Ideally, to avoid segregation, it is useful to mix powders with very close characteristics. Particle size is the most important factor. Normally, all the powders should have the same particle size. It is therefore necessary to mill and sieve them before mixing so that they present the same size. However, every substance has its own properties, and the same size does not mean the same shape and the same other properties.

The density of each component affects the stability of the mixture. The heavier particles have a tendency to fall

to the bottom while the lighter ones rise to the top of the powder bed.

The amount (proportion) of each component is also another factor. Good homogeneity is more difficult to obtain if the proportion of one component is small. It is very important that this small amount is perfectly distributed throughout the whole mixture, for example, when a very active substance is diluted in a large amount of excipient to facilitate dosage form preparation and administration (same problem for coloring). So, it is recommended, first to mix together small quantities of constituents and then continue progressive additions. It is also possible to introduce small amounts of drug substances into the mixture, as a solution in a volatile solvent. After mixing, the solvent is evaporated.

Some mixtures need the addition of an adjuvant; thus, to mix magnesium oxide and charcoal, it is necessary to use alcohol or etheroxide, which are evaporated after mixing.

If these factors are not under control, segregation (demixing) can occur. Powder particles can be separated in a mixing device because their pathways depend on their size and density: this happens in rotating shell mixers. Segregation can also be seen when mixer is emptied, when powder is discharged, or during transport and storage. Due to vibrations, there are free spaces in which denser particles can slip and fall to the container's bottom. This separation is facilitated by the size and shape of the particles, which can slip more or less over each other. For very fine powders, density differences are more important than particle adhesion and friction. No segregation is seen for particles under 40 μm diameter. Three types of segregation have been described:

1. Percolation segregation is the movement of the small particles through the voids in the static powder bed.
2. Trajectory segregation occurs during mixing: particles are set in motion and kinetic energy is imparted to them. Larger particles have larger energies and tend to move a greater distance into a powder mass before they are brought to rest. This may result in preferential separation and can occur in both horizontal and vertical planes.
3. Densification segregation: density differences between particles may cause segregation. Large particles move upward through the mass. It seems that the small particles beneath dense large particles are slightly compacted, supporting the large particles. On vibration, the small particles move beneath the large particles and raise them upward in the bed.

The effect of mixing time on segregation is that nonsegregating mixtures continue to improve with an

extended mixing time, but the reverse may be true for segregating mixes.

The factors promoting segregation require a longer time to establish a segregation mix that is needed to produce a reasonable degree of mixing. It is therefore counterproductive to prolong the mixing time beyond an optimum point.

Equipment

The three primary mechanisms responsible for mixing are (10) convective movement of relatively large portions of the bed, shear failure that primarily reduces the scale of segregation, and diffusive movement of individual particles.

Most efficient mixers operate by all three mechanisms. Thus, mixing can be considered a random shuffling-type operation, involving both large and small particle groups and even individual particles.

The ideal mixer should rapidly produce a complete blend with as gentle as possible a mixing action to avoid damage. It should be easily cleaned and discharged, be dust-tight, and require low maintenance and low power consumption.

Laboratory equipment: The pharmacist most often employs the mortar and pestle for the small-scale mixing usually required for prescription compounding. However, spatulas and sieves may also be used occasionally. The mortar and pestle method combines comminution and mixing in a single operation.

Industrial equipment: Rotating-shell mixers or tumbling mixers are shown in Fig. 3. Drum-type, cubical-shaped, double-cone, and twin-shell blenders with their axis of rotation horizontal to the center of the drum on its axis increase crossflow and improve the mixing action. Cubical and polyhedron-shaped blenders with a rotating axis set at various angles are also available. Double-cone blenders or tumbling mixers have been developed; the Y-cone mixer (Fig. 3) is a good example

Fig. 3 Tumbling mixers.

Fig. 4 Ribbon mixer.

(13). On rotation the charge flows into the top two arms of the Y and then back into the third arm. Mixing by shear and diffusion takes place when the streams mingle. Time must be allowed for the mix to flow into the arms, and there is an optimum speed rotation. The zigzag blender is an extension of the twin-shell blender.

A fixed-shell mixer or agitator mixer is shown in Fig. 4. Also called ribbon mixer, it consists of a relatively long throughlike shell with a semicircular bottom. The shell is fitted with a shaft on which are mounted spiral ribbons, paddles, or helical screws alone or in combination. These mixing blades produce a continuous cutting and shuffling of the charge by circulation the powder from end to end of the trough as well as rotationally. The shearing action that develops between the moving blade and the trough serves to break down powder agglomerates. A more recent type of agitator mixer is the Nautamixer (Fig. 5) that consists of a conical vessel fitted at the base with a rotating screw fastened to the end of a rotating arm at the top. The screw conveys material toward the top where it cascades back into the mass.

Sigma-blade and planetary-paddle mixers are used for solid blending and as a step prior to the introduction of liquids (Figs. 6 and 7). This type of mixer rapidly breaks down agglomerates.

Vertical impeller mixers employ a screw-type impeller, which constantly overturns the batch.

Motionless mixers are part of continuous-processing devices with no moving parts. They consist of a series of fixed flow-twisting or flow-splitting elements.

Validation of the Mixing Process

The mixing process is validated by the verification of the homogeneity of mixed powders, for instance, by taking three samples at three different levels of the mixer (top, middle, and bottom) and determining the amount of different active substances in these samples. Each sample must be of the same size as in the kind of dosage form to be used. A mixing index can also be used.

Other characteristics of the mixed powder such as particle size, flavor, flow rate, and bulk density before and after tapping have to be verified.

Fig. 5 Nautamixer.

The process reproducibility is assessed by performing operation and verification three times. The validation result is considered correct if the amount of each active substance found in each sample and all the other characteristics evaluated are within the set limits (22).

CLASSIFICATION AND EXAMPLES OF POWDERS AS DOSAGE FORMS

They can be classified as a function of their route of administration.

Oral Administration

Mode of administration and packaging

They are generally administered in or with water or with other appropriate liquids. In a few cases, they can be

Fig. 6 Sigma-blade mixer.

swallowed as they are. Both single and multiple doses are available.

Multiple-dose powders, presented in band or metal box, require a measure to deliver the prescribed dose. Initially, it was an ordinary spoon, but given the different sizes and shapes of the spoons used worldwide, powder density, humidity, degree of settling, fluffiness due to agitation, and personal judgment of patients (selecting a full or half spoon according to be patient's mood), it has been decided to use other devices. They are generally special measuring plastic spoons on which the volume is indicated and corresponds to a weight of powder as a function of its density (this volume corresponds to an adult or child dosage).

Fig. 7 Planetary-paddle mixer.

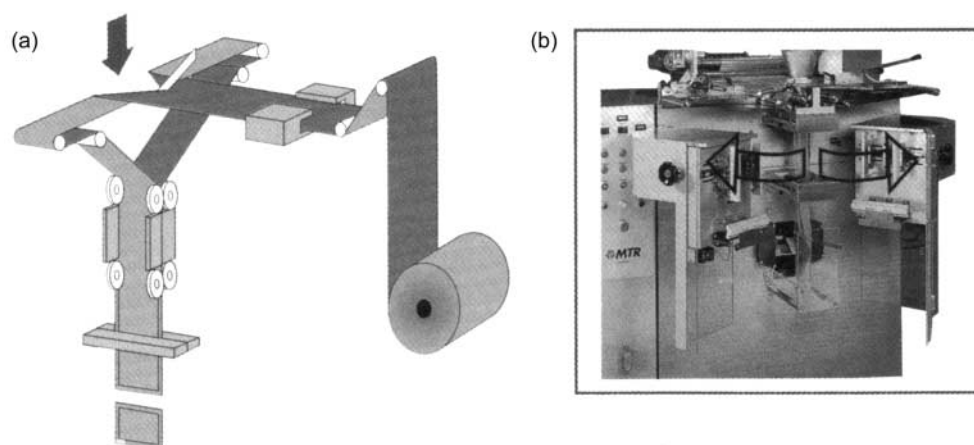

Fig. 8 (a) Foil preparation. (b) Multilane vertical sachet-filling machine. The hinged panels can be opened by 90° to allow complete access to the product dosing area, the film needed, and the sealing and cutting station.

Currently, the best way is to use single dose contained in a folded paper (in community pharmacy) or sachets filled with the same accuracy as a tablet or capsule by a fully automatic machine. The sachet is made of paper, aluminum, and/or complex mixtures that are a combination of aluminum and plastic substances. An aluminum or paper foil is covered on one or both sides (internal and/or external) with polyethylene, PVC, or PVDC (e.g., paper + polyethylene + aluminum + polyethylene). Generally, the foils are presented in rolls, printed on their outer face with the drug name, and assembled in automatic machines (Fig. 8) that use one or two rolls on which sachets are predrawn. First, the foils are cut longitudinally in a by-pass station and folded longitudinally. These folded paper webs are drawn off a roll, crosscut, and guided into presealed sachets. Powders are added by various devices (Fig. 9) such as

micropiston, vacuum feeding, volumetric drawer slide filler, dosing plates (or telescopic cups), suction devices, and discharge and filling funnels for non-free-flowing powders. After filling, the sachets are sealed (three or four side sealed sachets) at 100–145°C for 0.5 s. During filling, the weight must be controlled. After filling, the sachets are submitted to different controls such as sealing, integrity of foils, opening ease as well as permeability to gases, and to humidity. These controls are generally performed on the raw foils and on the finished products.

Excipients and/or modification of powder density or flow characteristics

To obtain a good filling, the powders must be homogeneous during the whole filling time and must flow regularly to obtain similar volume. Homogeneity is

Fig. 9 Different types of volumetric dosers.

obtained by the help of the mixing devices described previously. The mixers are connected to the filling machine. If the duration of mixing is increased, it is absolutely necessary to prevent uncontrolled demixing during this last step.

For the second point, it is necessary to know the flow properties of the powders, and generally it is compulsory to add some excipients to modify these properties and adapt them to the filling device.

The excipients used are fillers, but the most important are lubricants, such as magnesium stearate, PEG 6000, calcium stearate, glycerol palmito stearate, and calcium behenate, which increase the flowability but at the same time modify the hydrophobic characteristics of powders. Their choice depends on compatibility with active ingredient and the flow properties of powders. The characteristics of the excipient have been described previously.

Sometimes, it is necessary to modify the density of the powder by granulation made by the ordinary way (23) as for tablet preparation or using new techniques such as rotogranulation (24). This transformation is sometimes quite necessary because it is easier to modify the taste using flavoring substances or flavor modifiers (25). In this last case, a recent article describes the taste masking as a consequence of the organization of powder mixture (26).

Examples of powders as dosage forms

Effervescent powders: Initially these powders, described in the Pharmacopeia, consisted of sodium bicarbonate, tartaric acid, and potassium and sodium tartrate (wrapped in white paper). Each was separately dissolved in water and then mixed before drinking: they were called “English Seidlitz powders” (the Seltz or the English Soda powders are quite similar) (2).

Nowadays, effervescent powders are available in single or multiple units that contain acid substances and carbonates or bicarbonates, which quickly react in water by releasing carbon dioxide. They are dissolved or dispersed in water before being taken. This is a great advantage because the drug is then in solution, the pH of which is close to 7, which allows rapid passage through the pylorus. The drug absorption from the gut wall as well as the onset of therapeutic activity may thereby be hastened. Effervescent powders contain (27):

1. *Acid materials*

Acids: citric (monohydrate or anhydrate), tartaric, ascorbic (drug or excipient), fumaric, nicotinic, acetylsalicylic (as drug or excipient), malic, and adipic acids (seldom used).

Anhydrides: glutaric, citric.

Salts: sodium dihydrogeno-citrate, sodium acid phosphate, sodium fumarate.

2. *Sources of carbon dioxide*

Salts: sodium bicarbonate (the most widely used), sodium carbonate, potassium carbonate, calcium carbonate, sodium glycine carbonate (28).

3. *Other excipients* (main characteristic, solubility in water):

Lubricants: PEG 6000 is most frequently used, alone or with sodium stearyl fumarate, sodium benzoate, sodium chloride, sodium acetate, or D,L-leucine.

Binders: PVP, hydrogenated maltodextrin, maltodextrins, PEG 6000.

Others: sweeteners, flavors, colors, surfactants, anti-foaming agents (polydimethylsiloxane).

The manufacturing process requires a very low and controlled relative humidity (about 20% or less, if necessary) as well as a controlled ambient temperature close to 25°C. Generally, effervescent powders are made by classical wet granulation of the acid and carbonate part separately or mixed with water–ethanol or isopropanol. Special care must be taken in the case of total granulation to limit the effervescent reaction, except in case of use of the technique of granulation with a rotor (29).

The stability and shelf-life of effervescent powders are essentially assured by protection against external moisture. Single-dose sachets are manufactured with suitable complexes to prevent premature reaction caused by external moisture or excess internal moisture from the granulation process. Special stability studies under different conditions are required for these powders. The dissolution time must be less than 3 min; this is an index of stability.

Many drugs and drug compositions are used in effervescent products including aspirin, acetaminophen, ibuprofen, nonsteroid-antiinflammatory drugs, cimetidine, antibiotics, mucolytic drugs, vitamins, and others. It has been demonstrated many times that drugs are rapidly, and sometimes better, absorbed in this form than in conventional dosage forms (30, 31).

Powders for Parenteral Use

For parenteral use, solid sterile substances are distributed in their final packages. A clear solution nearly free of particles or a uniform one is obtained after shaking with the prescribed volume of an appropriate sterile liquid. Freeze-dried substances for parenteral use are also used.

After dissolution or dispersion, preparations must comply with assay requirements for injectable preparations or injectable preparations for perfusion. Their preparation requires the same care as parenteral solutions, i.e. sterilization of raw material or finished product sterilization (32).

Powders for Cutaneous Applications

These are single- or multiple-unit powders free of agglomerated particles. They must be sterile for application on open wounds or damaged skin.

Multiple-unit powders for local application are preferably packaged in a dredger or a pressurized container (for skin, teeth, or vaginal douche use). These preparations consist of a dispersion of a solid phase (drug) in a liquid propellant (liquid phase). By action on the actuator, the suspension is released by gas pressure. The propellant in contact with ambient air is evaporated and the powder remains on the treated area. The particle size obtained depends on the powder particle size before the preparation of the suspension.

Many powders are presented in this special dosage form (e.g., antiseptics, antifungal drugs) as well as cosmetic preparations (dry shampoo, etc.). Generally, the drug is mixed with an inert diluent such as starch, magnesium carbonate, magnesium stearate, or silicon dioxide of particle size close to 50–60 μm . To increase the suspension stability and to prevent closure of the actuator,

lubricants and/or surfactants are added (mineral oils, isopropyl myristate, lecithin, sorbitane fatty acid esters). These last substances will also prevent agglomeration or crystallization of drug substances (percentage about 0.1–1%).

The propellants used were some years ago chlorofluorocarbons (CFCs) (11 and 12) in various proportions (65:35 or 50:50). The manufacturing process includes the suspension formation in liquid propellant 11 in a cooled and hermetically closed mixer containing drug and lubricants. This mixture is introduced in the cans that are closed by a special powder valve, and propellant 12 was then injected through the valve. The upper part of the valve has often a special aperture through which a gaseous phase cleans the valve as well as the actuator.

A major current issue is the suppression of the use of CFCs due to ozone depletion. Other liquid propellants (134a, 227, or dimethyl ether) are not used as easily as the CFCs and formulation is very difficult. So, many of these dosage forms disappeared or were substituted by “saltcellar” systems. The use of very volatile solvents, such as volatile silicone, can be proposed if their boiling point is close to room temperature (33), the use of butane is not recommended due to the explosion risks.

Powders for Pulmonary Application

As a consequence of the suppression or reduced use of CFC propellants, a new kind of dosage form is under

Fig. 10 Spinhaler.

worldwide development: drug powder inhalers (DPIs). The metered dose inhalers (MDIs) will probably be replaced by these. The MDIs were formulated several years ago. A drug in powder form (with a particle size close to $5\text{ }\mu\text{m}$) was suspended in propellant 11 with a surfactant. Propellant 12 was added to the can after closure.

The metered valve delivers a fixed volume of suspension that after propellant evaporation, releases the active drug in the upper respiratory tract. Owing to its small diameter size, about 10% of the drug reaches the bronchopulmonary tract and provides therapeutic activity.

Currently, propellant issues have led companies to develop DPI. These consist of a very fine active drug (particle size $5\text{ }\mu\text{m}$ or less) mixed with an inert excipient such as lactose. The mixture is administered through a special device.

Spinhaler (Fisons) (Fig. 10) and Rotahaler (Allen and Hanbury) (Fig. 11) were introduced more than 10 years ago for delivery of single metered doses of sodium cromoglycate, salbutamol, or beclomethasone dipropionate in powder form, with the energy required to disperse the powder being derived from the patient's own inspiratory effort. Both the Spinhaler and Rotahaler (Ciba systems) are rather inconvenient to use because it is necessary to load a gelatin capsule containing the drug powder into the device immediately prior to use. However, a lot of new multidose dry powder inhalers have been recently introduced. The Diskhaler (Allen and Hanbury) contains eight doses of either salbutamol or beclomethasone dipropionate (2-day supply at normal dosing levels) in blisters around the periphery of a small disk. The Diskus is more interesting: it contains 60 doses of antiasthmatic drug

with a special counter, which indicates the number of delivered doses. The Turbuhaler (Astra) (Fig. 12) contains 200 metered doses of the bronchodilator terbutaline sulfate in the manner of a pressurized MDI, but without additives of any kind. The corticosteroid budesonide is available in a Turbuhaler in some countries.

The clickhaler is based on the same principle: a reservoir containing a number of doses releases one after an actuation.

It seems that all these devices are easy to use and are readily accepted by patients. According to some authors, they deliver a similar percentage of the drug dose to the lungs as a correctly used MDI and has an equivalent efficacy (34).

However, patients with low inspiratory flow rate (essentially children) have many difficulties to use them. Furthermore, when the particles are inhaled quickly, their inertia increases and there is an impaction in the throat. So, new devices are developed to improve the patient's compliance. They consist of a pump that compresses air in a special chamber so that the powder is expelled as a cloud, owing to the pressure delivered by the compressed air (35). These systems are close to the old MDI.

CONCLUSION

The preparation of powders as dosage forms comprises many steps that are the same as for the preparation of powders used to manufacture other solid dosage forms such as tablets or hard gelatin capsules.

Fig. 11 Rotahaler.

Fig. 12 Turbuhaler.

Years ago powders were used as dosage forms more frequently before the advent of more modern forms. However, biopharmaceutical problems arose with these new drug dosage forms, and companies have returned to powders and developed these further. Industrial sachet manufacturing considerably reduces handling and improves storage. Pressurized systems allow easy dispensation of disinfectants, which increases patients' compliance. It can be expected that powders will continue to be used in the future.

PRESERVATION OF PHARMACEUTICAL PRODUCTS

Peter Gilbert

David G. Allison

University of Manchester, Manchester, United Kingdom

PRESERVATION

Microbial spoilage of pharmaceutical products has been known for many years. Spoilage may result in the deterioration of the product due to loss of potency or to the initiation of an infection in the user. Sterile pharmaceutical products (single dose or multiple dose forms) require the addition of an antimicrobial preservative when they have been manufactured under aseptic conditions from presterilized ingredients. Where the products are subject to a terminal sterilization process, only the multiple dose category requires the addition of an antimicrobial agent. In the latter instance, the preservative is added to protect the product and end user against the consequences of microbial entry during use. Chemical antimicrobial agents are thus added to all multidose sterile formulations and to aqueous and aqueous-based nonsterile pharmaceuticals. Their function is to reduce the microbial load to a level, which is safe for the designated use of the product, and to maintain the numbers of viable microorganisms at or below that value for the storage and use life of the product. Preservatives must, therefore, be stable within the formulation for the shelf life of the product and be capable of dealing with all the abuses made to it by the consumer and user (i.e. contamination during use, incorrect storage *etc*). Table 1 presents, in alphabetical order by chemical grouping, the agents most often employed for preservation of pharmaceutical products.

For multidose sterile products, the preservative must be capable of reestablishing sterility between each use, whereas for a nonsterile topical cosmetic the function of the preservative might simply be to prevent growth. The associated toxicity of preservatives often limits the concentrations at which they can be employed; thus, lower concentrations are generally employed for ophthalmic products and injectables. In choosing a preservative the likely capacity required, the rate of killing desired, and the ingredients and pH of the formulation must be borne in mind.

The BP (1988) test for the "Efficacy of Preservatives in Pharmaceuticals" makes it quite clear that a preservative

must in the first instance *kill* microorganisms and only accepts later that it will prevent growth. However, it does insist that there must be no outgrowth of the test organism, that is, the preservative possesses sufficient residual capacity to inhibit the growth of any survivors.

DEFINITION OF TERMS

Disinfectants, antiseptics, and preservatives are chemicals that have the ability to destroy or inhibit the growth of microorganisms, and are used for this purpose. These and other terms commonly employed are defined as follows:

- *Disinfectants*: Chemical agents or formulations that are too irritant or toxic on body surfaces, but are used to reduce the level of microorganisms from the surface of inanimate objects to one that is safe for a defined purpose.
- *Antiseptics*: Chemical agents or formulations that can be used as an antimicrobial agents on body surfaces.
- *Preservatives*: Chemical agents or formulations that are capable of reducing the number of viable microorganisms within an object or field to a level that is safe for its designated use and will maintain the numbers of viable microorganisms at or below a level for the use/shelf-life of the product.
- *Bacteriostasis*: A state in which the growth of microorganisms is halted or inhibited.
- *Bactericide*: A chemical antimicrobial agent that reduces the viability of a population of microorganisms exposed to it. This term is meaningless without specifying the concentration range over which this effect is obtained; such concentration ranges will vary between different species of microorganisms.
- *Bacteriostat*: A chemical antimicrobial agent that can prevent the growth of microorganisms within an otherwise nutritious environment. This term is meaningless without specifying the concentration at which this effect is achieved. Bacteriostatic concentrations do vary between different species of microorganisms.

Table 1 General properties of some widely used preservatives

Preservative	Advantages	Disadvantages	Application
<i>Acids (organic):</i> benzoic acid, parabens, sorbic acid	Active against bacteria and fungi	Highly pH dependent	Oral and topical formulations; gums and syrups
<i>Alcohols:</i> ethyl or isopropyl, chlorbutol, bronopol	Broad spectrum, including that against acid-fast bacteria	Volatile; poor penetration of organic matter	Solvent; eye drops and injections; synergistic properties
<i>Aldehydes:</i> formaldehyde, gluteraldehyde	Broad spectrum antibacterial, antifungal, and sporicidal activity	Acid solutions inactivated with temperature; toxic and carcinogenic	Chemical sterilization and storage of surgical instruments (e.g., endoscopes)
<i>Biguanides:</i> chlorhexidine, polyhexamethylene biguanide	Mainly active in cationic form against gram-positive bacteria	Water insoluble; inactivated by organic matter; limited antifungal activity	Solution for hard contact lenses and other ophthalmic products
<i>Halogens:</i> hypo-chlorite, povidone-iodine, chloroform	Broad spectrum of antibacterial, fungal, and viral activity	Unstable; corrosive; inactivated by organic matter	Limited use nowadays
<i>Organic mercurials:</i> mercury, silver, thiomersal, phenylmercuric acetate	Broad spectrum of antibacterial activity	Low capacity to organic matter, ionic and some nonionic surfactants; toxicity	Eye drops; contact lens solutions
<i>Phenolics:</i> cresol, chlorocresol, bisphenol	Cheap, rapid activity against gram-positive bacteria and fungi	Low water solubility; adsorbed by rubber; volatile, irritant, pH dependent	Creams
<i>Quaternary ammonium compounds:</i> cetrimide, benzalkonium chloride	Narrow spectrum (gram-positive bacteria) of activity; surfactant properties	Low capacity to organic matter; low activity at acidic pH; incompatible with soaps, ionic and nonionic surfactants	Eye drops; surgical creams; ointments

It should be noted that terms such as bactericide and bacteriostat should be discouraged; in the USP and EP, the term "antimicrobial agent" has replaced these terms.

PRESERVATIVE IDEALS

At present there is no perfect preservative, and all materials are a compromise of a number of often contrary properties. The following are the properties of an ideal preservative compound and need to be considered when choosing a preservative.

1. *Definable in chemical terms*: Many of the existing preservatives, such as the quaternary ammonium compounds, are mixtures of various homologues. Often the activity obtained is a function of the mixture composition. Unless it is possible to define and control mixture composition, the performance of the agents will be variable, even if they conform to a pharmacopoeial specification.
2. *Broad spectrum of activity*: The compounds must possess a broad spectrum of antimicrobial activity against all species of microorganisms and also toward bacterial endospores. In practice, the only compounds that meet this requirement are formaldehyde, glutaraldehyde, hypochlorite, and ethylene oxide. All these compounds are highly irritant at sterilizing concentrations to be used in pharmaceutical products. Formaldehyde is, however, used at low concentrations in some shampoos; in these cases contact with the skin is short-lived and irritancy minimal. Agents such as quaternary ammonium compounds, phenolics, and the parabens group possess good activity against gram-positive bacteria but little or no activity toward spores. Certain gram-negative organisms such as *Pseudomonas aeruginosa* are virtually resistant to these agents. Generally, antifungal activity is difficult to obtain. Combinations of preservatives are sometimes employed to widen the spectrum of activity to include molds, bacteria, yeasts, and endospores.
3. *Effectiveness*: The compounds must be effective over a wide range of pH in order to be effective in all formulations. In practice, compounds are generally more active at either acid or alkaline pH. Thus, the pH of a formulation determines the types of preservative suitable for inclusion.
4. *Stability*: The compounds must be stable to light and elevated temperatures for the expected shelf life of the product. The effects of pH upon stability should be minimal. In this respect it is worth noting that the

preservative Bronopol is stable only in the dark and at an acid pH. Under alkaline conditions or in the light it rapidly decomposes to give formaldehyde at concentrations that would be ineffective as a preservative. Instability to light can be protected against the packaging in a light-proof container. Storage tests must be performed on all formulations to ensure that adequate levels of preservative remain at the end of then expected shelf life of the product.

5. *Solubility*: Preservatives should ideally be used at concentrations much lower than that of the main constituents of the formulation. Their solubility ought to be such that it is possible to add them as a concentrated solution and where there is no danger of creating a saturated solution.
6. *Aesthetics*: Preservatives should have no perceptible odor, color, or taste, which might affect the aesthetic qualities of the final product. This can be of crucial importance for a cosmetic product but is less important for medical ones.
7. *Volatility*: Preservatives should be nonvolatile. Thus, chloroform is not an ideal preservative as it is lost from the formulation each time it is exposed to air.
8. *Product incompatibility*: Preservatives should not be incompatible with any of the likely excipients within the product formulation. This would include incompatibilities with the container material and also the active ingredients. In practice this is very difficult to achieve.
9. *Toxicity*: At the concentrations employed, the preservative should be nonirritant, not cause hypersensitivity reactions, and be nontoxic. In this respect, the site of application is critical. Relatively few compounds are approved for use in ophthalmic products due to their high sensitivity towards xenobiotics. Also, compounds safe for use on intact skin might be hazardous for inclusion in parenteral products.
10. *Solubility in oil*: Preservatives must not be too oil soluble as this can produce problems in two- and three-phase systems where the preservative accumulates in the oil and micellar phases and is unavailable for antimicrobial action in the biological (aqueous) phase. It is worth noting that the oil:water partition coefficient can alter as a function of pH and also as a function of the nature of the oil.
11. *Cost*: The preservative must be cost-effective in the context of the overall product positioning (i.e., cost of goods ratio).

Although a very large number of antimicrobial compounds have been examined for their suitability for preservation of pharmaceuticals, only a few (<20) are

currently used in the majority of pharmaceutical products. Moreover, in many cases, the “least unsuitable” rather than the “optimum” preservative is selected for a particular product.

DYNAMICS OF PRESERVATION

The critical lethal parameters of the effectiveness of antimicrobial agents are the concentrations of the agents employed, the time of exposure, the types and numbers of organisms exposed, the pH of the environment or formulation, and the temperature of application. An understanding of the effects of these conditions upon the killing process and of the terms that describe such dependence is important to rationalize the use of preservatives in different situations and formulations.

Time of Contact

When exposed to lethal concentrations of a chemical antimicrobial agent, the viability of a bacterial population decreases exponentially with time (Fig. 1). Such pseudo-first-order kinetics can be described by the equation

$$\frac{S}{S_0} = Ae^{-kt} \quad (1)$$

$$\log \frac{S}{S_0} = kt + \log A \quad (2)$$

where k is the rate constant, S is the number of surviving organisms at time t , and S_0 is the initial number of viable organisms within the population.

D -value is the time for 90% kill. That is,

$$\log S - \log S_0 = -1 \quad (3)$$

and

$$D\text{-value} = 1/k \quad (4)$$

In practice, such obedience to first-order kinetics is rare for chemical inactivation. More commonly, deviations from first-order kinetics are obtained, when there is either an initial lag in the rate of killing (Fig. 2A) or when the rate of killing decreases with time of exposure (Fig. 2B). The former is commonly observed when the concentrations of preservative are minimally bactericidal and reflects the time required for injuries caused to the bacterial cells to assume lethal proportions. Such plateauing therefore decreases as concentrations of agent employed become greater (Fig. 2A) and are inapparent at

Fig. 1 Time survival kinetics for the inactivation of a bacterial population by treatment with a chemical agent. The D -value represents the time taken, at a given concentration of biocide, to reduce the surviving population by 90%.

very high concentrations. The second effect reflects the presence of resistant organisms within the population, capacity effects on the action of the preservative, or failure of the neutralizer. In such cases commonly observed with quaternary ammonium compounds and biguanides, the levels of kill at the plateau value increase with increasing concentration of preservative. From these relationships, an estimate of the initial rate of killing (k) or the D -value (actual time to effect a 90% reduction in viability) can be made, but their predictive value must be questioned.

Approximation to first-order kinetics implies that the sensitivity toward preservatives of a population of micro-organisms is normally distributed. Decreases in the rate of killing with time often results from adsorptive loss of the preservative onto and into the killed cells, causing a

Fig. 2 Deviations from first-order kinetics of the inactivation of microbial populations by treatment with chemical agents due to (A) an initial lag in the rate of killing or (B) a decrease in the rate of killing with time of exposure.

decrease in the available concentration of the preservative for killing the surviving organisms. The susceptibility of preservatives to such adsorptive losses is described as its capacity.

Exponential decreases in viability with time mean that total elimination of all living cells cannot be guaranteed. Rather, knowing the initial size of the population and its susceptibility, the probability of having achieved sterility might be assigned to particular inactivation processes. Such assignments assume, often wrongly, that first-order kinetics are universally applicable.

Concentration of Preservative

The efficacy of an antimicrobial agent varies as a direct function of its concentration. At very low concentrations the antimicrobial effect might be negligible, at intermediate concentrations the effects might be growth-inhibitory, whereas only at relatively high concentrations might they be bactericidal. Often different mechanisms of action are involved to bring about these different effects. For example, chlorhexidine inhibits growth through direct effects upon respiratory enzymes and ATP synthesis, but kills through causing gross permeability changes to the bacterial cell envelope. The minimum growth inhibitory concentration (MIC) of an agent gives little or no information about its bactericidal activity, but might indicate weaknesses in the overall antimicrobial spectrum of activity. Minimum lethal concentrations can range from $2 \times \text{MIC}$ – $20 \times \text{MIC}$, dependent upon the antimicrobial substance and target organism. In the bactericidal range, the concentration exponent (η) describes the dependence of activity on concentration. This can be obtained as the slope of a graph of $\log D$ or k versus \log concentration. Although these values vary slightly among organisms, they are fairly characteristic of compound groups and also often relate to mammalian toxicity. Thus, compounds with high concentration exponents more readily lose their biological activity when diluted upon parenteral administration than those with low exponents (Table 2).

The concentration exponent gives no indication as to the level of activity of a particular agent. It only indicates the degree of dependence of activity upon concentration. If the \log_{10} of a death time is plotted against the \log_{10} of the concentration, a straight line is usually obtained, the slope of which is the concentration exponent. Given the D -value for a single concentration and concentration exponent, it is possible to calculate (from Eq. 5) the activity at any other concentration. As different antimicrobial mechanisms are often involved in growth inhibition and killing, the use of concentration

Table 2 Some examples of preservative concentration exponents

Compound	Exponent
Organic mercurials	0.9–1.0
Iodine	0.9–1.0
Formaldehyde	1.0–1.1
Benzalkonium chloride	0.8–2.5
Bronopol	0.7–0.9
Parabens	2.5–3.0
Phenolics	4.0–9.9
Aliphatic alcohols	6.0–12.7

exponents to extrapolate MIC data to bactericidal situations should be avoided.

$$(\eta) = \frac{(\log \text{Dat}C_2 - \log \text{Dat}C_1)}{\log C_1 - \log C_2} \quad (5)$$

The value of the concentration exponent also gives an indication of the susceptibility of the agent to inactivation by dilution and/or losses in activity through adsorption of the agent on organic debris or killed bacterial cells. The loss of an antimicrobial agent from solution in this manner relates to concentration in solution and absorptivity rather than to the inherent antimicrobial activity of the agent. The activity and concentration exponents of four hypothetical agents are described (Fig. 3). Agents A & B and C & D have similar concentration exponents

Fig. 3 Comparisons of the activity and concentration exponents of four hypothetical preservatives. Agents A & B and C & D have similar concentration exponents but different activities, whereas A & C and B & D have similar activities yet different concentration exponents.

but different activities, whereas A & C and B & D have similar activities yet different concentration exponents.

If isotoxic concentrations of each agent (equivalent *D*-value) are employed, and undergo a uniform drop in concentration through adsorption, the compounds with the higher activity will undergo the greatest loss of activity (*A* & *C* > *B* & *D*). For compounds of similar activity, the one with the higher concentration exponent will have the greatest activity loss (*A* > *C* and *B* > *D*). This can be generalized in the statement that capacity is inversely related to both the concentration exponent and activity. Preservatives used in sterile products generally have high concentration exponents and high activity. Such considerations are also helpful in determining inactivation conditions for the preservatives prior to sterility and preservative effectiveness tests.

Temperature Effects

The rate of killing of an antimicrobial agent is directly dependent on the temperature of the interaction. This dependence is described by the temperature coefficient (*Q* or *θ*), which can be determined either from the slope of the graph relating the *D*-value or *K* and temperature, or from Eq. 6.

Temp. Coefficient [*θ*_{*t*₁–*t*₂}]

$$= \frac{D\text{-value } t_2(D_2)}{D\text{-value } t_1(D_1)} = \frac{kt_1}{kt_2} \tag{6}$$

The subscripts denote the temperature range over which the change in activity is defined. This is commonly given as the coefficient per 10°C rise (i.e., *θ*₁₀ or *Q*₁₀), but is sometimes quoted for 1°C and 25°C changes.

Although the temperature coefficients vary a little between organisms, they are characteristic for particular preservative groups (Table 3). A high *θ*₁₀ value renders a compound suitable for application at elevated temperatures but unsuitable for the preservation of formulations that might be stored over a wide temperature range.

It should be noted that the temperature will also affect the degree of ionization in some circumstances; therefore,

Table 3 Temperature coefficients (10°C) for some commonly used preservatives

Compound	<i>θ</i> ₁₀
Aliphatic alcohols	30–50
Phenolics	3–5
Formaldehyde	1.5
Chlorocresol	6.0
Organic mercurials	1.0

the concentration exponent for some compounds will be apparently affected by temperature.

Effect of pH

The degree of ionization of acidic and basic antimicrobial agents depends on pH. Some compounds are active only in the unionized state (e.g., phenolics) whereas others are preferentially active as either the anion or cation. It therefore follows that the activity of a particular concentration of an agent will be enhanced at a pH that favors the formation of the active species. Thus, cationic antibacterials such as acridines and quaternary ammonium compounds are more active under alkaline conditions. Conversely, phenols and benzoic acid are more active in an acid medium. Chlorbutol is less active above pH 5 and unstable above pH 6. Phenylmercuric nitrate is only active at above pH 6 whereas thiomersal is more active under acid conditions. The sporicidal activity of glutaraldehyde is considerably enhanced under alkaline conditions whereas hypochlorites are virtually ineffective at above pH 8.

Knowledge of the *pK_a* of a preservative allows the calculation of the fraction undissociated at any particular pH and hence (via the concentration exponent) the level of activity at that pH.

Fraction of undissociated biocide

$$= \frac{1}{1 + \text{antilog } (pH - pK_a)} \tag{7}$$

The pH also affects activity by altering the net surface charge on the microorganisms. Thus, as pH is decreased, the surface becomes less negative and adsorption and thereby activity of cationic agents is reduced. These effects are greater for gram-negative than gram-positive bacteria.

Presence of Interfering Substances

In most instances, before an antibacterial agent can act on a cell, they must first combine. The presence of other materials, commonly referred to as organic matter, may reduce the effect of such an agent by adsorbing or inactivating it and thus reducing the amount available for combining with target cells. Extraneous matter may be able to form a protective coat around the cell, thereby preventing the penetration of the active agent to its site of action.

PRESERVATIVE INTERACTIONS

Until the late 1930s, cosmetic and pharmaceutical formulations were stabilized with soaps. Although preservatives

were often required, spoilage was only rarely a problem. With the advent of new materials for emulsion stabilization, preservation of the systems, or the lack of it, became a major problem. Nowadays we are aware of apparent incompatibilities between the new excipients and the established preservative agents and of the many interactions that can lead to preservative failure. No all-embracing set of rules have emerged to enable the "correct" preservative to be chosen for each formulation; only general guidelines exist.

The simplest form of interaction is one of adsorption/adsorption of the preservative from the formulation into and onto container and excipients. In this respect, it is convenient to divide these into colloidal excipients, suspensions, metal ions, and polymers.

Colloids

- **Gums:** Tragacanth, acacia, and plant polysaccharides such as agar and alginates are generally anionic in nature and will adsorb cationic preservatives such as chlorbutol, benzalkonium chloride, substituted phenols, phenylmercuric acetate, and merthiolates. Generally the adsorptive process increases with the increase in concentration of the gum or polysaccharide. Colloidal solutions of tragacanth and acacia, but not agar or alginates, can often be preserved with cationic agents by increasing the concentration of the preservative to saturate the colloid. For preservatives such as parabens, the problem is exacerbated at alkaline pH when the preservative becomes fully ionized.
- **Starches:** These bind substituted phenols but this can be overcome by increasing the concentration of the phenolic. Gelatin shows a slight interaction with the parabens group.
- **Proteins:** These interact both with cationic and anionic preservatives depending on to the pH of the formulation and the net charge of the protein.

- **Nonionic surfactants:** Interactions with a range of preservatives are unpredictable. Cationic and anionic surfactants interact and are contraindicated with anionic and cationic preservatives respectively.
- **Polyethylene glycols:** These interact particularly with the phenolic group of preservatives. The interaction increases with increase in molecular weight of the polymer. With increasing temperature, the extent of binding increases due to thermal desolving of the polymer and the creation of further binding sites.

Suspending Agents

These include clays, bentonite, kaolin, and talcs. They are generally anionic in nature and interact with most cationic agents. Inactivation depends on the pH of the system. Preservatives are only loosely associated with clays and therefore, desorb on dilution. The extent of these interactions are difficult to predict.

Container Materials

Nylon strongly adsorbs phenols and sorbic acid by covalent linkage. The degree of interaction depends on the pH, nature of the solvent, temperature, contact time, surface area, preservative concentration, and thickness of the nylon.

Acrylates and polyethylene affect most preservatives, including organic mercurials, phenolics, and benzoic acids. Leaching of hydroxyl ions from glass raises the pH and indirectly affects preservative activity. In this respect, glass must pass a "limit-test" for alkalinity.

Changing the container of a product from glass to plastic can alter its preservation. The container is as much a part of the formulation as is the product that is placed in it. Equally, adsorption and absorption into rubber closures can be significant, as exemplified by the phenolics (Table 4).

Table 4 Loss of preservative through absorption into rubber caps

Preservative	Initial concentration (% w/v)	Final concentration (% w/v)	Percentage loss
Phenol	0.5	0.39	22
Cresol	0.3	0.21	30
Chlorocresol	0.1	0.04	60
Phenyl mercuric nitrate	0.001	0.00005	95

PRESERVATION OF TWO-PHASE SYSTEMS

When preservatives are added to two-phase oil–water systems, depending upon the hydrophilicity of the agent, they partition between the two phases. Bacteria will only grow within the aqueous phase or at the oil–water interface. Thus, preservative lost to the oil is unavailable for antibacterial action. Hence the concentration in the water phase is reduced, affecting the rate of kill, but the capacity of the system is unaffected as preservative lost by adsorption onto organic debris and bacteria is replaced from that held in the oil.

The distribution between the oil and water phases is easily predicted from the oil–water partition coefficient, K_w^0 (Eq. 8)

$$K_w^0 = \frac{\text{Concentration in oil}}{\text{Concentration in water}} \quad (8)$$

By knowing the concentration of preservative required for the necessary biological effect in the aqueous phase (C_w), the oil: water phase ratio (θ) and the K_w^0 for the system, C , the concentration needed in the formulation, may be calculated from the expression

$$C_w = \frac{C(\theta + 1)}{K_w^0 \theta + 1} \quad (9)$$

It is also worth noting that altering the nature of the oil can affect partition coefficients quite dramatically, for example, the differences between vegetable and mineral oils (Table 5).

If the preservative favors the oil, increasing the oil: water ratio dramatically decreases available concentration; if it favors the aqueous phase, the reverse occurs and can cause solubility problems. Unfortunately, both temperature and pH also affect K_w^0 , in addition to the effects of pH directly on the activity of the preservative.

Table 5 Partition data for various preservatives

Preservative	K_w^0	
	Mineral oil	Vegetable oil
Chlorocresol	0.5	11.7
Methyl parabens	0.02	7.5
Propyl parabens	0.5	80.0
Butyl parabens	3.0	280.0
Cetrimide USP	<1.0	<1.0
Bronopol	0.043	0.11
Phenonip	>1.0	>1.0
Phenyl mercuric nutrate	<1.0	<1.0

PRESERVATION OF THREE-PHASE SYSTEMS

Most oil–water systems contain surfactants as emulgens in order to provide a stable emulsion. Some preservatives may associate directly with the surfactants whereas others may partition into the micellar phase of the surfactant, treating it as a third phase for partitioning.

These effects can be calculated to some extent, where C_w depends not only on K_w^0 but also on surfactant concentration. Initially it is assumed that the surfactant micelles form part of the aqueous phase. Thus, if K_w^0 is the oil:aqueous phase partition coefficient and C_A the total aqueous concentration, then, as in Eq. 9,

$$C_A = \frac{C(\theta + 1)}{K_A^0 \theta + 1} \quad (10)$$

Now

$$C_w = \frac{C_A}{R}$$

where

$$R = C_A/C_w \text{ that is } C_A = RC_w.$$

As

$$K_w^0 = C_A/C_w \text{ and } C_0 = K_w^0 C_w,$$

substitution in Eq. 9 gives

$$C_A^w = \frac{C(\theta + 1)}{C_0/C_A^{\theta+1}} \quad (11)$$

and substituting once again for C_0 ,

$$C_A = \frac{C(\theta + 1)}{(K_w^0 \frac{C_w}{C_A \theta}) + 1} \quad (12)$$

Substituting in Eq. 12 for $C_A = RC_w$ gives

$$RC_w = \frac{C(\theta + 1)}{(K_w^0 C_w / RC_w \theta) + 1} \quad (13)$$

which then reduces to

$$C_w = \frac{C(\theta + 1)}{[K_w^0 \theta + R]} \quad (14)$$

Eq. 14 allows the active concentration in the water phase to be calculated from C , the phase ratio (θ), K_w^0 and R . This is useful as K_A^0 varies with the concentration of the surfactant. R can be found from a graph relating

C_A/C_W and surfactant concentration, where the slope of the line is k .

$$R = 1 + k[\text{surfactant concentration}]$$

All preservative manufacturers provide values of k for a range of surfactants.

TOXICITY AND SAFETY CONSIDERATIONS

There are certain limitations on the use of antimicrobial preservatives based on their toxicity and potential side effects. The British Pharmacopoeia recommends that the maximum quantity of an injection containing an antimicrobial preservative to be administered at a single occasion is 15 ml. The USP, on the other hand, recommends a maximum of 5 ml. These maximum volumes must be considered when toxicity data and concentrations of the agents included in the formulations are considered. The final concentration of any substance employed is a balance between its potential toxicity and antimicrobial activity. Additionally, because meninges are readily irritated, the inclusion of antimicrobial preservatives in any formulation that might gain access to the cerebrospinal fluid is precluded. Intracardiac and intraarterial injections must also not contain an antimicrobial preservative.

It is not surprising that preservatives sometimes prove toxic to humans. To assess the toxicity of any substance, it is necessary to know its acute and cumulative toxicity together with its "no effects levels" and also to be aware of its mutagenic, teratogenic, and carcinogenic potential. In addition, its local actions as well as its liability to cause hypersensitization might be important. Any new preservative must be subjected to a battery of such mandatory tests to provide these data as must a new application of an established biocide.

ACUTE TOXICITY

Preservatives, for the most part, are used at very low concentrations and the question of their acute toxicity rarely arises. The margin of safety is not always very high, however.

SUBACUTE AND CHRONIC TOXICITY

When substances are given repeatedly, manifestations of toxicity may differ, particularly if the compound is given

at a rate faster than what the individual can detoxify or excrete. Some preservatives contain mercury and this may accumulate in the body.

REPRODUCTIVE TOXICITY

As part of the general safety testing of all preservatives, consideration is given to possible effects in higher animals on the fertility of either sex, the gestation or postnatal care, and development of the embryo. No direct causal relationships have been shown between any of the commonly used preservatives and reproductive toxicity. However, indirect reproductive toxicity has been suggested, for example, benzoic acid as a preservative, increases blood salicylate levels, and may cause a significant increase in the teratogenic potential of aspirin. Organic mercury has been shown to be responsible for a congenital form of Minamata disease, but not at levels likely to be taken into the body through mercury-containing preservatives.

CARCINOGENICITY AND MUTAGENICITY

Several preservatives have been scrutinized for being possible carcinogens, and their use regulated (e.g., chloroform and formaldehyde). Another possibility is that the preservative interacts with amines or amides to form carcinogenic nitrosamines. Published data on the mutagenicity of preservatives is limited as tests such as the Ames test can only be carried out at concentrations far less than those employed.

PRESERVATIVE COMBINATIONS

The ideal properties expected from preservatives are not met by any of the current, established agents. All chemical agents have their limitations in terms of their antimicrobial activity, resistance to organic matter, stability, incompatibility, irritancy, or toxicity. It is also unlikely that new preservatives will be developed because of high costs of putting a new compound through toxicity tests and the likelihood of a new compound being impossible to cover by patent. More likely preservative combinations will be employed in the future, possibly to give synergistic combinations (e.g., hydrogen peroxide and peroxygen compounds, chlorhexidine and cetrimide). In this manner,

Table 6 Examples of interactions between preservatives

Preservative A	Preservative B		
	Synergistic	Additive	Antagonistic
Benzalkonium	Phenylmercurics	3-Cresol	Hexachlorophane
Benzoic acid	Dehydroacetic acid	Parabens	Boric acids
Bronopol	Benzalkonium	Sorbic acid	—
Chlorbutanol	Phenylethanol	—	EDTA, EGTA
Chlorocresol	Phenylethanol	—	—
Phenylmercurics	3-Cresol	—	—
Parabens	Germall	Benzoic acid	Boric acid
Sorbic acid	Dehydroacetic acid	Benzoic Acid	Parabens

preservative combinations may be used to extend the range and spectrum of preservation (Table 6); for example, by combining a series of alkyl esters of 4-hydroxybenzoic acid, water solubility is decreased to such an extent that both the aqueous and oil phase of an emulsion are protected.

When acting simultaneously on a microbial population, combinations of preservatives may cause an increased, decreased, or unchanged antimicrobial response when compared with their summed individual effects. A minimum requirement of any combination should be that it achieves at least the same level of protection overall as the individual components do. Ill-considered preservative combinations may lead to inclusion of irrelevant agents. In general, agents from the same chemical group or those having the same mode of action are likely to produce merely additive effects whereas those exhibiting different mechanisms or sites of action may serve either to reinforce (synergize) or reduce (antagonize) their individual activities. Such effects may be evaluated by preparing mixtures of the two preservatives being investigated and determining their growth inhibitory power by an MIC determination. Results may then be plotted in the form of a graph, termed an isobologram, an example of which is shown in Fig. 4.

In general, synergistic effects can occur through three different mechanisms. The first mechanism is by inhibition of inactivation. Here, one compound increases the effective concentration of the other by inhibiting the microbial system responsible for its inactivation. To date, however, there are no reported observations of this mechanism with preservatives. The second synergistic mechanism is very common amongst preservatives and occurs when one compound increases the accessibility of targets to another. This usually occurs when one agent

exerts its action by increasing the permeability of the cell wall or cell membrane. Besides damaging the cell in its own right, this can permit access (or increased access) of the second compound to targets that were previously concealed. An example of this type of synergy is seen in the cooperative action between benzalkonium chloride and thiomersal which disrupts the cytoplasmic membrane, thereby facilitating access of organomercurial agents that react with sulphhydryl-containing enzymes in the cytoplasm. This type of synergy does not necessary require

Fig. 4 Isobologram showing three possible outcomes of interaction between preservatives A and B, namely (A) antagonism, (B) additivity, and (C) synergy.

both compounds to possess significant antimicrobial activity. Finally, perhaps the broadest category of synergistic interactions is that in which two compounds act simultaneously at different targets, thereby significantly influencing the biochemistry of the cell. Although these targets must be different in order to produce synergy, they can be closely related. For example, the synergy between chlorocresol and 2-phenylethanol is thought to be through their respective effects on the generation and coupling of a proton gradient to active transport.

There are many significant practical benefits and advantages of preservative combinations. These include an increased spectrum of activity; the need for lower

concentrations of each of the individual components, thereby possibly reducing potential toxicity; the prevention of resistance to individual preservatives; possible enhancement of antimicrobial activity beyond that expected by simple addition; an extended time course of preservation achieved by combining a labile, markedly biocidal preservative with a stable longer-acting ingredient. Furthermore, careful selection of individual agents for combination, based on their physicochemical properties, may serve to overcome microbiological problems created by the physical limitations of individual preservatives. In this respect, factors affecting preservative efficacy must be carefully considered.

PROCESS CHEMISTRY IN THE PHARMACEUTICAL INDUSTRY

Kumar G. Gadamasetti

ChemRx Advanced Technologies, Inc., San Francisco, California, U.S.A.

Ambarish K. Singh

The Bristol-Myers Squibb Pharmaceutical Research Institute, New Brunswick, New Jersey, U.S.A.

INTRODUCTION

In the pharmaceutical industry, identification of a development drug candidate (preclinical lead profile, PLP, or early candidate notification, ECN), filing of investigational new drug application (IND), and new drug application (NDA) are important milestones before the launch of a new drug. The IND and the NDA are the events where the industry interacts with the Food and Drug Administration (FDA) prior to launching. Various governmental departments play specific roles in furthering drug development programs. The medicinal or discovery chemists identify the new drug candidates to treat or prevent a particular medical indication, whereas the process chemists are responsible for devising a synthesis and supplying the active pharmaceutical ingredient (API) or bulk drug substance (BDS) in multigram quantities for various studies needed to file the IND and support other drug development programs. On approval of the IND, the compound can be administered to humans for the first time as part of the phase-I clinical studies, also known as first-in-man (FIM) trials. Studies that are reported in an IND include synthesis, animal toxicology, pharmaceuticals and formulation, drug substance and drug product stability and safety, and metabolic and pharmacokinetics.

The clinical development is the most expensive and resource-intensive segment of the process. Process research and development play a key role in shortening the overall timeline from candidate identification to drug launch. On an average, it takes about 10–15 years from discovery to launch a drug into the market at a cost in excess of \$400 million. The paradigm shift (in the 1990s) of increasing the number of compounds entering development has made a tremendous impact on chemists responsible for preparing supplies of these new drug candidates. Early and effective interaction of process research personnel with medicinal chemists and early innovations in process development are believed to shorten the IND and NDA timelines, respectively. These overall reduced timelines would allow for an early launch of the drug into the market (1).

PHARMACEUTICAL DRUG DEVELOPMENT EVENTS: THE CHEMIST'S VIEWPOINT

A simplified view of the pharmaceutical drug development events (not to the timescale) is given in Fig. 1.

Genomics to Lead Development Candidate (PLP)

During the past decade, the pharmaceutical industry has seen a paradigm shift in the drug discovery process. The driving force for such change, arguably, was propelled by a variety of factors, including

- Generation of new targets (for human diseases) from advances in genomics and functional genomics.
- Advances in combinatorial chemistry methods to increase the number of compounds for high throughput screening (HTS), and
- Advances in automation and high-throughput screening techniques for rapid identification of lead compounds.

Although these approaches promise to provide an increased number of novel drug candidates for evaluation in the treatment of a greater number of diverse diseases, successful realization of the potential benefit of these compounds is very much dependent on the ability of the pharmaceutical industry to develop suitable manufacturing processes.

PLP Development Candidate to IND and the Kilo Lab

The IND studies require relatively large amounts of the drug substance, substantially more than what was prepared during the course of the medicinal chemistry programs. Generally, it becomes the responsibility of the process research group to produce this material within the shortest feasible time frame (2). Most of the major pharmaceutical companies have kilo-lab facilities as an interface between the process research labs and the pilot plants. Pharmaceutical process groups are organized in different ways. In some companies, process research is responsible for

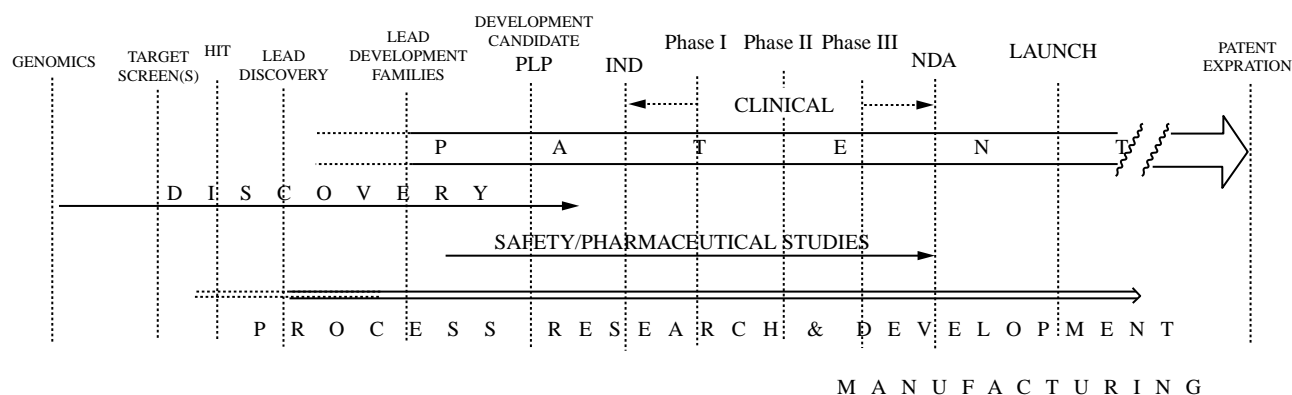

Fig. 1 Pharmaceutical drug development events, a simplified view. *Preclinical*: Medicinal chemistry, combinatorial chemistry, process research. *Clinical*: Process R&D & manufacturing (operations).

providing the supplies of BDS required for an IND filing, including the initial clinical batch (or batches). Typically, the initial supplies are prepared by the combination of modified medicinal chemistry synthesis and new, alternative synthetic processes more suitable for scale-up. In some companies, the chemists in process research labs and kilo labs share this responsibility. Kilo-lab scale-up work typically is performed in 22-L glassware and small reactors (50–100 L). The process development group, on the other hand, is responsible for further optimization and scale-up in the pilot plant and interfaces with the manufacturing.

Clinical Phase, NDA, and Launching of the Drug

The clinical phase (phase I) of the drug development begins after the IND where humans are subjected to the clinical trials. After a successful phase-I trial, efficacy of the drug is tested on a large number of patients as part of the phase-II/III clinical trials. Once the phase-II/III clinical trials are completed, the NDA is filed with the FDA. Clinical trials and NDA are prerequisites for launching the drug.

PROCESS RESEARCH AND DEVELOPMENT

The goal of the medicinal or drug discovery chemist is to identify a new lead to treat or prevent some particular medical indication and define a synthetic strategy to allow for the preparation of as many analogs as possible. The focus of process chemistry differs from routine organic chemistry. It emphasizes optimization and defines the controls to make the sequence of chemical reactions amenable to scale-up. A viable process should reliably yield

a high-purity product made by a process unencumbered by a patent. In short, the overall thrust of the scientists engaged in process chemistry is to develop the shortest, least expensive, safest, and most environmentally friendly processes to produce the API in multi-kilogram quantities.

The term “process” is, in general, misinterpreted as scale-up work by the overwhelming majority of the scientists and technologists involved with drug discovery and development programs in the pharmaceutical industry. Scientists and engineers engaged in the various aspects of pharmaceutical process research and development have a highly refined appreciation for the challenges of large-scale synthesis and the purification of the API. An algorithm for process research and development is shown in Fig. 2.

The mission of process chemistry in the pharmaceutical industry is to provide documented, controlled synthetic processes for the manufacture of the supplies to support the development programs and future commercial requirements of the API. The science and technology associated in accomplishing this mission provide a tremendous challenge to the individuals or the group of individuals for the drug supply progress from milligram to metric ton quantities.

Fig. 2 Algorithm for process research and development.

Route Scouting

As the development drug candidate moves from discovery to process, a workable synthesis is available, which, however, may not be scalable. Route scouting plays a key role in identifying synthetic transformations that are safe, practical, scalable, cost effective, and environmentally friendly, thus setting the stage for eventually delivering a manufacturing synthetic process. An integral part of route scouting is to identify key intermediates that could be easily outsourced.

An example of route scouting and process improvements

Scheme 1 depicts the medicinal chemistry approach to the synthesis of BMS-180291 (Ifetroban).

A condensed schematic of the overall alternative synthesis of BMS-180291 (Ifetroban) is provided in Scheme 2.

The synthesis of the key acid ester intermediate A has been reduced dramatically from 16 to 4 steps, and the yield has been increased 10-fold from 5 to 52%. The overall synthesis of Ifetroban has been cut virtually in half (from 23 to 12 steps) and the yield (via the longest linear sequence) improved from 3 to 28%.

Process Development and Optimization

Human safety is the first priority when developing a process, followed by quality (purity, crystallinity of the product, etc.) and product yield. In addition, the process chemist takes into account the following factors:

- Hazards associated with the chemical step (human and equipment safety).
- Waste generated (disposal cost, environmental concerns).

Scheme 1 Original synthesis of BMS-180291.

Scheme 2 Alternative synthesis of BMS-180291.

- Cost and availability of raw materials, reagents, and solvents (cost of goods, sourcing issues).
- Ease of performing the reaction on-scale (savings in capital and labor).
- Ease of product isolation (crystallization), and
- Opportunity to combine two or more chemical steps with no intermediate isolation (telescoping to increase throughput).

Once a route has been selected, the next step is to understand the effect of interactions of variables with each other on the reaction yield and quality for each and every step of the synthetic scheme and to define the limits for these process variables. This requires designing appropriate experiments including controls. This is important because as the scale of the reaction increases, every unit operation, such as addition of reagents, solvents, distillation, phase splits, etc., takes a considerably longer time. Mixing begins to play a major role as the size of the vessel increases. Due to uneven mixing, localized differences in variables such as temperature and

concentration are expected, which may have an adverse effect on the reaction.

Example 1: Process development of BMS-182205 (Scheme 3)

Issues: environmental concerns, human safety, waste management, process inefficiency.

The first step in the synthesis of the Paclitaxel[®] side chain has been reported in the literature by Holton (4). The drawbacks of this procedure from a process development standpoint are

1. The use of benzene and dichloromethane (human and environmental concerns).
2. No opportunity for telescoping (since the first reaction is conducted in benzene and the second in dichloromethane).
3. Low yield (68% after crystallization from ethylacetate and hexane), and
4. Brown-black product (color).

Scheme 3 Synthesis of BMS-182205.

Process improvements: *Phase I.* Benzene was replaced with a safer solvent, toluene, which was also used for the [2 + 2] cycloaddition reaction, thus facilitating the telescoping of the two reactions. However, dichloromethane was added during the work-up to prevent product precipitation. The product was crystallized from 2-propanol in 80% yield. The phase I of development eliminated the use of benzene and allowed for telescoping of the two chemical steps. However, a solvent exchange from toluene–dichloromethane to 2-propanol was still needed to crystallize the product. The color of the product after this modification was dark brown.

Phase II. Additional crystallization studies revealed that the product could be crystallized from toluene–heptane and acetone–water. The product also exhibited limited solubility in toluene. With this information at hand, both reactions were conducted in toluene as before; however, during the work-up, dichloromethane was not added. Instead, aqueous hydrochloric acid was added to neutralize excess triethylamine. Heptane was then added to precipitate the product directly from the reaction mixture. The crude wet product was crystallized from acetone–water with an overall yield of 80%. The color of the product was brown. The advantages of this modification are the elimination of several extraction and back-extraction steps and a reduction in processing time and in solvent consumption.

In an attempt to further improve the yield and address the product color issue, the following process variables were studied: the rate of addition of acetoxyacetyl chloride, the reaction temperature, and the effect of other amine bases.

The rate of addition of acetoxyacetyl chloride was optimized to be 2–3 h, at 3, 10, and 17°C. Reactions conducted at 3°C afforded the product with the highest quality. Two amines, *N*-methylmorpholine (NMM) and diisopropylethylamine (DIPEA), were evaluated in addition to triethylamine. In the presence of NMM, the reaction stopped after 65% conversion. In triethylamine the reaction took an additional 3 h for completion, after the addition of acetoxyacetyl chloride. However, in DIPEA, the reaction was instantaneous, the yield was further improved to 87%, and the product was free of brown-colored impurities.

Example 2: Process development of Ifetroban (Scheme 4)

Issues: environmental concerns, human safety, cost of goods (5).

In the improved synthesis of Ifetroban described previously, environmental concerns due to special handling of copper bromide waste and hazards associated with hexamethylene tetramine (HMT) on manufacturing scale led to further perfection of the synthesis. Mechanistic considerations suggested that an oxidized form of aminoamide *B* (Scheme 4) would eliminate the necessity for a late-stage copper-mediated oxidation. This was indeed accomplished. The cyclization–elimination sequence was initiated by a Lewis acid and completed by base-mediated elimination to afford the Ifetroban penultimate. In addition to eliminating the need for copper bromide and HMT, this modification helped to reduce the cost of the product by an additional 15%.

Scheme 4 Process development of Ifetroban.

Manufacturing process, route from medicinal chemistry to multi-kilos for clinical study supplies:

A highly optimized and concise large-scale synthesis of a purine bronchodilator was developed by the Astra Production Chemical company from Sweden (6). Supplies for the initial biological studies were generated by the medicinal chemistry route shown in Scheme 5. The overall yield was about 14%, which was improved in the environmentally friendly manufacturing process to about 51% (Schemes 6 and 7).

Process Hazards and Safety

Process safety has become an integral part of the development of new synthetic routes, and more and more relevant information is gathered in typical process development labs (7). Many development facilities have now established special process safety departments with state-of-the-art equipment and well-trained personnel. It is important for process chemists considering alternative process routes to know the potential hazards from the main reaction and from the unwanted side reactions in each case so that the hazards of reactivity are included in the factors

reviewed in developing and selecting the final process route; three main parameters determine the design of safe chemical processes:

1. The potential energy of the chemicals involved and understanding of the inherent energy (exothermic release or endothermic absorption) during a chemical reaction.
2. The rates of reaction (energy release in the form of heat or pressure) that depend on the temperature, pressure, and concentrations. In any hazard evaluation process, the rates of reaction during normal and abnormal operations (including the worst credible case) must be considered in order to design an inherently safe process.
3. An equipment train must adequately remove any heat or pressure generated in a reaction. The effects and requirements of scale-up must be considered.

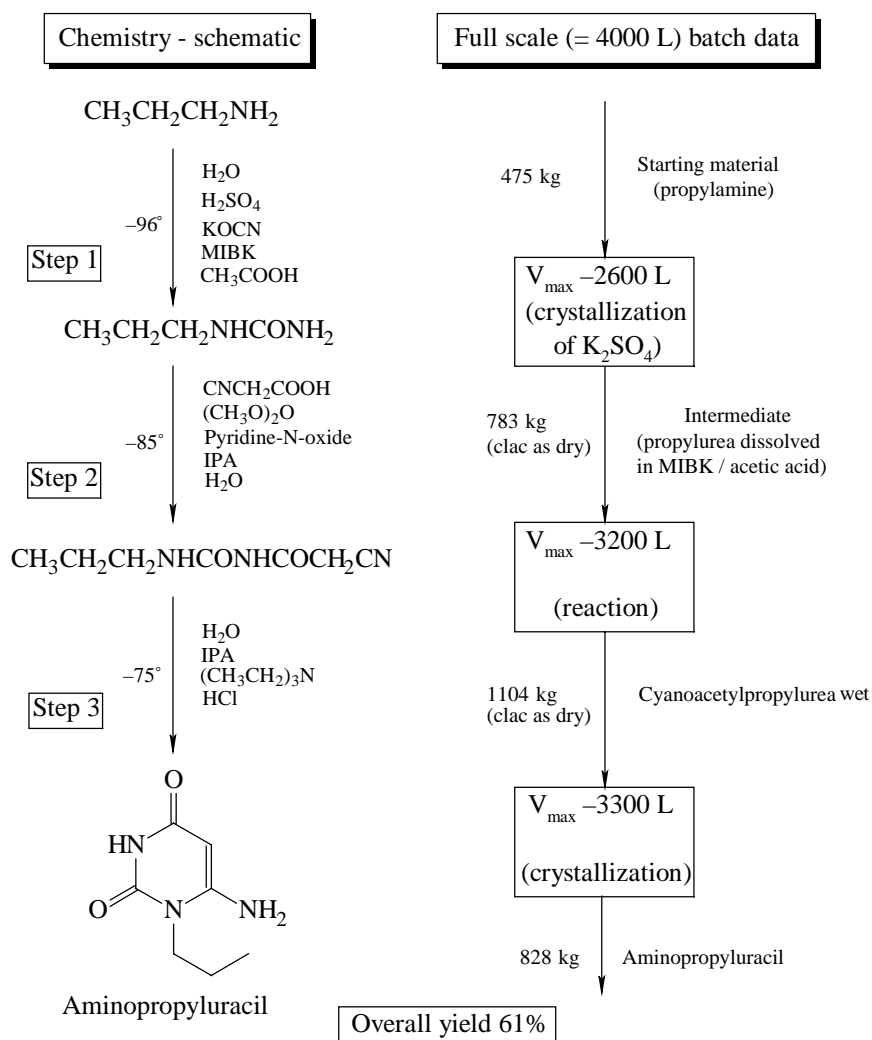

In most cases, a team of development chemists, engineers, and safety personnel evaluate and assess hazards associated with each and every step of a process, from performing a reaction to storage of waste streams in drums. The team recommends a set of safety experiments to be conducted, and data are collected for reaction

Scheme 5 Original synthesis of enprophylline by the medicinal chemistry department at Astra.

exotherms, powder explosivity, gas evolution, and compatibility of reaction mixtures or reaction waste with pilot-plant equipment and storage drums. Experiments are designed and conducted to determine the potential for initiation of a runaway reaction and the effect of decompositions that may occur on runaway. Based on the safety assessment of a process, appropriate measures are taken in the pilot plant to eliminate or minimize any hazard. During the early stages of process research (route

scouting), only small amounts of materials are available. In many cases, only theoretical information from the literature or from calculations is readily available. Screening tests can be run to identify the reaction hazards. As the route-scouting efforts enter the process development phase, additional material becomes available so that the reaction hazards can be studied more extensively to test “what-if” scenarios. During full-scale production, the chemical hazards may be reevaluated to address changed

Scheme 6 Astra commercial process of 6-amino-1-propyluracil.

production requirements or other process changes such as the use of a different source of raw materials.

Numerous test methods are available using a variety of sample sizes and conditions. The tests provide qualitative or quantitative data on onset of temperature, reaction enthalpy, instantaneous heat production as a function of temperature, maximum temperature, and/or pressure excursions as a consequence of a runaway, and additional data useful for process design and operation.

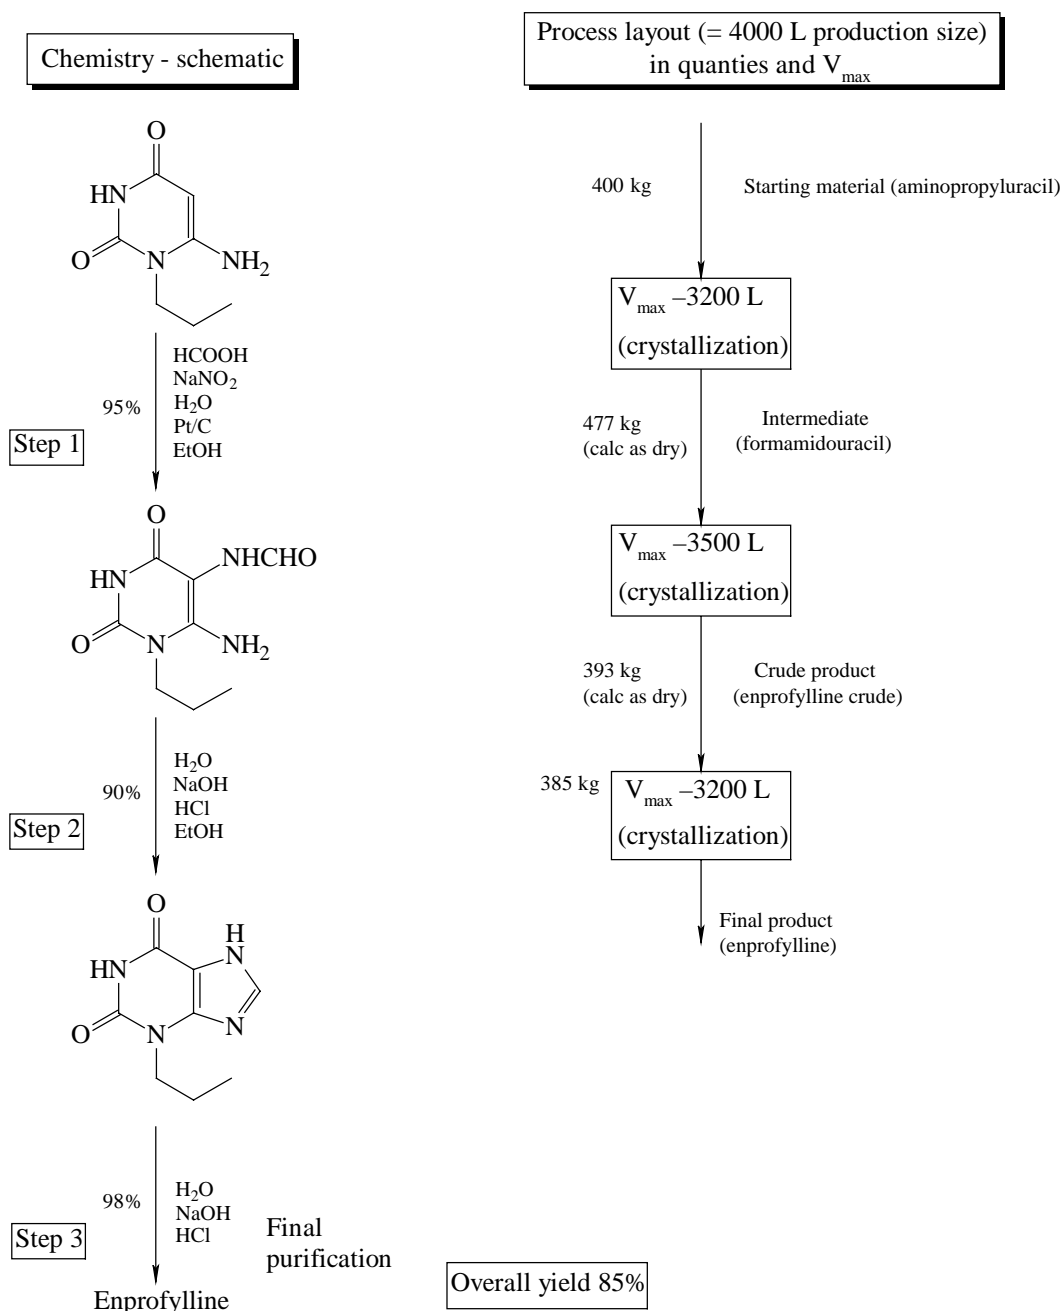

“Green Chemistry”: Environmental Concerns

The research that involves the end-of-process treatments to eliminate pollutants is termed “green chemistry.” As Ronald Breslow (Columbia University) pointed out (8), concern for the environment is as old as the biblical injunction, “hurt not the earth, neither the sea, nor

the trees.” The following example indicates approaches to the environmentally benign chemistry. The process described is high yielding with water as the by-product. Sato et al. (9) have developed an efficient, environmentally friendly method for oxidizing primary and secondary alcohols (Scheme 8). The Japanese scientists use hydrogen peroxide as an oxidant, a quaternary ammonium hydrogen sulfate as a phase-transfer agent, and tungsten as catalyst.

Enzymatic Intervention

The recent trend in pharmaceutical industries is to incorporate a microbial technology (MT) or enzymatic technology division in the process R&D and manufacturing (need basis) departments. The role of the MT division is usually to provide pharmaceutical drugs

Scheme 7 Astra full-scale synthesis of enprofylline from 6-amino-1-propyluracil.

(e.g., pravastatin, β -lactam drugs, etc.), and chiral (optically pure) building blocks or synthons for the ongoing synthetic programs.

A number of cholesterol-lowering drugs (Pravachol, Zocor, and Mevacor) are prepared by enzymatic processes. Penicillin antibiotics that have been in the market for decades are produced in large quantities by the enzymatic process.

Enzymatic catalysis

The extensive use of enzymatic catalysts in organic synthesis has been documented (10–13). Enzymes represent a broad range of efficient chemical catalysts. They are classified mainly into six categories:

1. Hydrolases (hydrolysis of amides, esters, glycosides, and lactones)

2. Isomerases (C–C bond migration, E/Z isomerization, and racemization)
3. Lyases (addition to π -bonds)
4. Oxidoreductases (reversible oxidations and reductions)
5. Synthetase formation and breaking of C–C, C–N, C–O, C–S, and phosphate ester bonds
6. Transferases (transfer of acyl, glycosyl, or phosphoryl groups from one molecule to another)

Scheme 9 gives three examples.

Design of Experiments (DOE)

An understanding of how various process variables affect the chemistry is necessary for the design of a chemical process (14) that can reliably provide the product in high yield and quality. This understanding can be obtained from experimentally determined rate laws for the main and side reactions that relate temperature, concentration, pressure, solvent effects, and equivalents of each reagent to yield and impurity levels. The process chemist may take the approach of evaluating the importance of process variables by changing one variable at a time. This method can help generate chemical knowledge but is not efficient and does not easily provide the quantitative information needed to rank the importance of process variables. Furthermore, the process chemist is often faced with a task of quickly scaling up the synthesis without the benefit of completely understanding the mechanism of the chemistry involved. With the aid of statistical design approach, a great deal of

useful information can be obtained with relatively few experiments. Statistical approaches involving factorial designs are ideal for studying processes where the underlying principles are not well developed or are extremely complicated.

Factorial experiments consists of a systematic variation of two or more process variables at a time. For a two-level experiment, each variable is set to a high or a low value according to a standard pattern. An experimental run is conducted for each possible combination of variable settings. Selection of the low and high levels for each variable is important for obtaining meaningful results. If the levels selected are too close together, the calculated effect could be no larger than the experimental noise. Selecting widely separated levels could result in running the reaction under unrealistic conditions, for example, above the solvent boiling point, or above the decomposition temperature for reagents and reactive intermediates.

Data analysis of factorial designs involves a comparison of the experimental responses at the high and low settings of each variable. The results can be plotted in several different ways to develop an understanding of the effect of changing two or more process variables at a time with regard to reaction yield and quality of the product.

Drug Substance Crystal Form (Final Form)

The crystal form of the drug substance (15) is important for pharmaceutical industries, where products are specified not by chemical composition but by their performance. Good crystallinity, good bioavailability, satisfactory aqueous solubility and dissolution rate, and satisfactory physicochemical properties, such as stability, hygroscopicity, and flowability are required. Choosing the appropriate crystal form (final form) often involves crystallizing the drug substance from various solvent systems to search for polymorphism and screening of various salts of the drug substance (if chemically possible).

The chemical, biological, and physical characteristics of the drug substance can be manipulated and hence optimized by conversion to a salt form. Every compound that exhibits acid or base characteristics can participate in salt formation. Various salts of the same compound often behave quite differently because of the physical, chemical, and thermodynamic properties they impart to the parent compound. Table 1 lists the top 10 FDA-approved commercially marketed final drug forms, and Table 2 lists the top 10 salts that are not approved by the FDA but that are in use in other countries. Only salts of organic compounds have been considered here because most drugs are organic substances. The relative frequency with which each salt

Scheme 8 Noyori's oxidation of alcohols.

Scheme 9 Enzyme-mediated chemical transformations. (a) Enantioselective enzymatic oxidation and lactonization; (b) enzyme reduction with baker's yeast and enantioselective rule; and (c) enzymatic hydrolytic desymmetrization.

type has been used is calculated as a percentage, based on the total number of anionic or cationic salts in use.

The salt form is known to influence a number of physicochemical properties of the parent compound, such as dissolution rate, solubility, stability, and hygroscopicity. These properties, in turn, influence the absorption, distribution, metabolism, and excretion of the drug. This knowledge is essential for a complete understanding of the onset and duration of action, the relative toxicity, and the possible routes of administration. For example, certain

salts of the strong base choline have proved to be considerably less toxic than their parent compound. This observation led to the preparation of choline salicylate as an attempt to reduce the gastrointestinal (GI) disturbances associated with salicylate administration. Clinical studies indicated that choline salicylate elicited a lower incidence of GI distress, was tolerated in higher doses, and was of greater benefit to the patient than was acetylsalicylic acid (aspirin).

The chemical and physical stability of a drug can influence the choice of dosage form, the manufacturing and packaging, and the therapeutic efficacy of the final preparation. Systematic determination of the thermal stability, solution stability (at various pHs), and light sensitivity of a drug and its derivatives, both alone and in the presence of additives (excipients), provides essential information toward selecting the most suitable salt and dosage forms.

Depending on the mechanism of degradation, different salt forms impart different stability characteristics to the parent drug. Sparingly soluble salts used in the formulation

Table 1 Salts approved by the FDA

Anion	Percent	Cation	Percent
Hydrochloride	43	Sodium	62
Sulfate	7.5	Potassium	11
Bromide	5	Calcium	10.5
Chloride	4	Zinc	3
Tartrate	3.5	Meglumine	2.3

Table 2 Salts not approved by the FDA

Anion	Percent	Cation	Percent
Glycerophosphate	0.88	Piperazine	0.98
Aminosalicylate	0.25	Bismuth	0.98
Aspartate	0.25	Diethylamine	0.33
Bisulfate	0.25	Tromethamine	0.33
Hydroiodide	0.25	Barium	0.33

of suspensions reduce the amount of drug in solution and hence its degradation. Differences in hygroscopicity of several salts influence the stability of the drug in the dry state. For example, the stability of penicillin G and its salts has been widely studied because of the drug's therapeutic importance and its characteristic instability.

A solution of penicillin is not stable beyond two weeks even at refrigerator temperatures. However, the use of suspensions of sparingly soluble amine salts (procaine and hydrabamine salts) in aqueous vehicles allowed marketing of a "readymade" penicillin product.

Crystallization of the drug substance and its salt forms

In academia, a synthetic organic chemist rarely thinks about isolating a compound by crystallization, unless a single crystal structure is required. Most of the time, the chemist depends upon column chromatography to purify the compound. In contrast, in the pharmaceutical industry much depends upon crystallization. For example, crystal morphology and particle size have a direct impact on the filtration of a crystal slurry, cake compressibility, bulk stability and dissolution, bulk density, and flow characteristics. Crystallization is the preferred way of isolating the product from a reaction mixture. Knowledge of various crystallization systems from which the drug substance could be crystallized can provide information on polymorphism, thus expediting the selection of final crystal form. In polymorphism, two crystal forms with the same molecular structure are distinguished by the way in which the molecules are packed within the crystal lattice; each form has distinct physical and thermodynamic properties. In 1998, Abbott Laboratories withdrew its HIV drug, Ritonavir, because of the unexpected appearance of a new crystal form that had different dissolution and absorption characteristics than the standard product (16).

Crystallization is generally preceded by two types of nucleation. The primary nucleation occurs with the formation of clusters of molecules at the submicron level. When the concentration exceeds saturation to afford supersaturation, the clusters become nuclei. The secondary

nucleation is caused by particles due to primary nucleation or seeds. There are many strategies to achieve supersaturation to initiate crystallization such as cooling, evaporation, and antisolvent addition.

Early on in the drug development program, only small amounts of material are available for crystallization studies. Parallel crystallization technique in test tubes allows for the identification of many solvent systems using small amounts of material. On a small scale, it is not easy to control the rate of cooling or the rate of evaporation to achieve supersaturation. However, the antisolvent addition strategy to achieve supersaturation in combination with seeding allows rapid identification of several crystallization systems using a minimum amount of compound.

Salts of a substrate having an acid or an amine functionality are prepared by dissolving the substrate and the counter-base (or acid) separately in appropriate solvents, mixing the two solutions in equimolar ratios, and removing the solvents under vacuum to afford a solid. This method has two distinct advantages: First, the composition of the substrate remains the same during various crystallization attempts, and second, this portion of the work can be automated with the use of liquid handling systems.

The next step is to determine the solubility of the substrate (or its salts) in different solvents. This can also be performed by an automated liquid handling system. Depending upon the solubility of the substrate in water-miscible solvents (alcohols, acetone, tetrahydrofuran, etc.) and water-immiscible solvents (ethyl acetate, methyl-*tert*-butyl ether, heptane, etc.), the process chemist can identify one or many solvent systems from which the substrate (or its salts) could be crystallized using the antisolvent addition strategy.

Another crystallization technique is used when the isolation of a highly water-soluble compound in its salt form is required from aqueous reaction mixtures. This technique takes advantage of the common-ion effect and is based on the le Chatelier's principle, which states that, "if, to a system in equilibrium, a stress is applied, the system will react so as to relieve the stress." Thus, in aqueous solutions, the solubility of the compound in salt form can be reduced by adding large amounts of a common ion that is more soluble than the salt of the compound.

Example: BMS-187745 is a potent inhibitor of squalene synthase and an efficient cholesterol-lowering agent in orally dosed animals. The final step of the synthesis involved oxidation of the penultimate in water with hydrogen peroxide and formic acid. The disodium salt was chosen as the final crystal form. Because of

Scheme 10 BMS-187745 crystallization by salting-out.

extremely high solubility of the disodium salt in water, it cannot be extracted from water by common organic solvents. However, by employing the concept of the common-ion effect, the disodium salt can be easily crystallized from water. To accomplish this, the pH of the reaction mixture, after quench with hypophosphorous acid, is adjusted to the desired range of 6.05–6.25 (pKa of disodium salt of BMS-187745 is 6). In this pH range, sodium salts of formic, hypophosphorous, and phosphoric acids are present in high enough concentration to help lower the solubility of the disodium salt of BMS-187745 and effect crystallization (Scheme 10).

Automation in Process Chemistry Laboratories

Since the 1960s, automation has been the major tool for dramatically improving productivity (17–21). Automation techniques were introduced on the plant floor to

improve quality, increase safety, and streamline the work. Significant savings were realized initially from shorter delivery times, lower unit costs, smaller inventories, and fewer product failures. Due to an escalating cost of bringing a drug to market, companies are under immense pressure to shorten development time. The pharmaceutical industry has embraced new technologies in its discovery programs to increase throughput, generate precise data, and ensure accuracy.

Drug discovery scientists have already adopted tools such as combinatorial chemistry synthesizers; robotic systems for HTS; and software packages for computational chemistry, molecular modeling, and design of experiments to identify lead compounds (“hits”). As the number of “hits” grows, there is a potential for process R&D to become the “bottleneck.” The number of compounds that can enter process development is limited by the number of process chemists available to work on these compounds. Without some type of automated process development

machines to increase throughput, it will not be feasible to evaluate all the potential "hits." Created by the results from the HTS, demand for high-throughput development (HTD) tools is growing. Various companies, who in the past may have only addressed the needs of drug discovery scientists, are in the process of inventing and developing instruments that can be used by process chemists to perform many experiments in parallel. Examples of commercially available HTD tools are described below.

Parallel reactions

Charybdis Technologies: In the Calypso Reaction BlockTM, multi-well reaction arrays are designed for both solution and solid-phase synthesis applications. Well volumes range from 2 to 10 ml, pressures up to 207 kPa (30 psi), and temperatures from -80 to +180°C.

Quest Synthesis Technology: Quest 210 is designed for up to 20 reactions in 5- or 10-ml reaction vessels. Each of the 20 vessels can be efficiently stirred, heated, or cooled, and maintained under an inert atmosphere. Quest 205 is designed for synthesis on a large scale, with two banks of five 100-ml reaction vessels.

Argonaut Technologies: EndeavorTM allows parallel reactions under pressures up to 3.3 MPa (33 atm) and temperatures up to 200°C. Each of the eight vessels (working volume 15 ml) can be independently controlled for temperature, pressure, and gas delivery.

SurveyorTM: Suitable for parallel process development and optimization with online sampling and integrated HPLC analysis, it employs 10 reaction vessels (working volume 15–45 ml), with individually controlled reaction temperatures from -40° to +150°C, with the ability to reflux. Reagent addition, reaction parameter control, sampling, and HPLC injection are controlled by built-in software.

Bohdan Automation, Inc: The process development workstation can run up to 12 independent reactions with working volumes of 25 ml. The following operations are automatically carried out: reagent preparation and addition, individual heating, cooling, and mixing, reaction sampling and quenching, and transfer to optional HPLC or FTIR modules.

Parallel purification

Isco, Inc: The CombiFlashTM Sg 100c System is suitable for purifying 10–35 g of material. It provides time- or peak-based fraction collection with on-line UV detection and a linear and/or step gradient with two solvents at a flow rate of 10–100 ml/min.

The CombiFlash Si 10x System simultaneously purifies up to 10 samples, with a linear and/or step gradient with two solvents with a total flow rate of 10–100 ml.

Automated sample handling and analysis

Bohdan Automation, Inc: The Balance AutomatorTM offers a cost-effective alternative to manual weighing, reduces errors and operator tedium, and processes up to 120 samples per hour. This system can accommodate various container sizes and balances with the help of interchangeable parts.

Gilson: The Gilson 215 Liquid Handler is a versatile, large-capacity, septum-piercing liquid handler for safe and efficient transfer. It helps in transferring samples to other analytical systems or inject samples directly to an on-line HPLC system.

OUTSOURCING

Outsourcing covers a broad range of services (22). It can eliminate the need for additional staff, facilities, and/or equipment. Outsourcing in drug discovery and development is expected to continue its remarkable growth over the next decade as drug synthesis becomes more complex. This dynamic growth is due to a number of factors, including the ongoing consolidation in the pharmaceutical industry and a tight labor market. As larger companies consolidate, they seek synergies resulting in release of R&D personnel. Retrospectively, companies need to get more done with fewer internal resources and this promotes outsourcing. The tight labor market has made it increasingly difficult to recruit and retain staff, and many companies are turning to outsourcing to gain access to highly trained scientists who are available. Pharmaceutical companies are also looking into long-term relationships with outsourcing partners.

FDA GUIDELINES AND REGULATORY ISSUES

The guidelines on drug preparation (GLP and cGMP compliance) regulatory issues are described in details in the Center for Drug Evaluation and Research (CDER) by the FDA (23). A complete section is dedicated to API and the GMP issues. The readers are encouraged to seek the reference for further details.

PRODRUG DESIGN

Bernard Testa
Joachim Mayer

University of Lausanne, Lausanne, Switzerland

A CASE FOR PRODRUG DESIGN

Drug disposition and metabolism are of essential significance in pharmaceutical research because of the interdependence of pharmacokinetic and pharmacodynamic processes. Limited intestinal absorption, inadequate distribution, fast metabolism, and toxic metabolites are some of the causes of failure of drug candidates during development. To reduce the rate of attrition resulting from such pharmacokinetic defects, disposition and metabolic studies should be initiated as early as possible in the screening of lead candidates.

Avoidance of the foreseeable or proven pharmacokinetic defects thus assumes considerable significance in drug research. However, pharmacokinetic (PK) and pharmacodynamic (PD) optimization may not be compatible, meaning that efficacy at the target may be decreased or lost during PK optimization (1). A telling example of such a situation is provided by the novel drug class of neuraminidase inhibitors of therapeutic value against type A and B influenza in humans. Here, target-oriented rational design has led to highly hydrophilic, poorly absorbed agents such as Ro-64-0802, which shows very high in vitro inhibitory efficacy toward the enzyme but low oral bioavailability because of its high polarity (2). To circumvent this problem, Ro-64-0802 is marketed as Oseltamivir, its ethyl ester prodrug (Fig. 1). After intestinal absorption, the prodrug undergoes rapid enzymatic hydrolysis and produces high and sustained plasma levels of the active agent. As demonstrated by this example, the prodrug concept may thus prove to be a valuable alternative to disentangle PK and PD optimization. In other words, rather than attempting to improve lead candidates within a unitary rational design process, it may be that PK optimization can be achieved by the application of the prodrug concept to research compounds with high in vitro activity. Some of the concepts of interest in prodrug design are examined here.

OBJECTIVES AND PRINCIPLES OF PRODRUG DESIGN

Prodrugs are defined as therapeutic agents that are inactive per se but are predictably transformed into active metabolites (3, 4). As such, prodrugs must be contrasted with soft drugs, which are active per se and yield inactive metabolites.

Prodrug design aims at overcoming a number of barriers to a drug's usefulness (Table 1). The major objectives of prodrug design derive from these considerations and are also listed in Table 1.

Many successes have been recorded in prodrug design, and a large variety of such compounds have proven their therapeutic value. Several complementary viewpoints can be adopted when addressing prodrugs, namely, their chemical classification, their mechanism of activation (i.e., enzymatic and/or nonenzymatic), their tissue selectivity, the possible production of toxic metabolites, and the gain in therapeutic benefit (Table 2).

The chemical classification distinguishes between carrier-linked prodrugs (drugs linked to a carrier moiety by a labile bridge) and bioprecursors, which do not contain a carrier group and are activated by the metabolic creation of a functional group (4). In the former, the carrier moiety is often and conveniently linked to polar groups such as —OH, —NHR, and —COOH. Relevant examples of bioprecursors are provided by chemotherapeutic agents whose activation occurs by reduction in oxygen-deprived cells. Thus, the one-electron reduction of 3-amino-1,2,4-benzotriazine 1,4-dioxide to a cytotoxic nitroxide is believed to account for the antitumor activity of this bioprecursor (5). Such bioprecursors appear as a viable class of prodrugs because they avoid potential toxicity problems caused by the carrier moiety. However, attention must be given here to metabolic intermediates. A special group of carrier-linked prodrugs are the site-specific chemical delivery systems (6). Macromolecular prodrugs are synthetic conjugates of drugs covalently bound (either directly or via a spacer) to proteins, polypeptides, polysaccharides, and other biodegradable

Fig. 1 The structure of the neuraminidase inhibitor Ro-64-0802 and its ethyl ester prodrug Oseltamivir.

polymers (7). A special case is provided by drugs coupled to monoclonal antibodies.

Prodrug activation occurs enzymatically, nonenzymatically, or sequentially (enzymatic step followed by nonenzymatic rearrangement). As much as possible, it is desirable to reduce biological variability, hence, the particular interest currently received by nonenzymatic reactions of intramolecular cyclization–elimination (8) presented at length below. The problem of tissue or organ targeting is another important aspect of prodrug design. Various attempts have been made to achieve organ-selective activation of prodrugs, such as dermal delivery (9) and brain penetration (6). For example, the selective presence of cysteine conjugate β -lyase in the kidney suggests that this enzyme might be exploited for delivery of sulfhydryl drugs to this organ (10).

The toxic potential of metabolic intermediates, of the carrier moiety, or of a fragment thereof must also be kept in mind. This is illustrated by formaldehyde-releasing prodrugs such as *N*- and *O*-acyloxymethyl derivatives or Mannich bases. Similarly, arylacetylenes assayed as potential bioprecursors of antiinflammatory arylacetic

acids proved many years ago to be highly toxic because of the formation of an intermediate ketene. The gain in therapeutic benefit provided by prodrugs is an issue with no general conclusion. Depending on both the drug and its prodrug, the therapeutic gain may be modest, marked, or even significant. In the case of marketed drugs endowed with useful qualities but displaying some unwanted property, the expected therapeutic gain is usually modest to marked. In the case of difficult candidates showing excellent target properties but suffering from some severe physicochemical and/or pharmacokinetic drawback, a marked to significant benefit can be obtained.

CHEMICALLY ACTIVATED PRODRUGS: REACTIONS OF CYCLIZATION–ELIMINATION

So many biological factors may affect enzymatic reactions that the resulting interspecies and interindividual variability renders prodrug design unreliable and sometimes even problematic. To circumvent such difficulties, an increasing

Table 1 Barriers to drug usefulness and corresponding objectives of prodrug design

Pharmaceutical barriers	Pharmaceutical objectives
Insufficient chemical stability	Improved formulation (e.g., increased hydrosolubility)
Poor solubility	Improved chemical stability
Offensive taste or odor	Improved patient acceptance and compliance
Irritation or pain	
Pharmacokinetic barriers	Pharmacokinetic objectives
Low oral absorption	Improved bioavailability
Marked presystemic metabolism	Prolonged duration of action
Short duration of action	Improved organ selectivity
Unfavourable distribution in the body	
Pharmacodynamic barriers	Pharmacodynamic objectives
Toxicity	Decreased side effects

(From Ref. 3.)

Potential toxicity
Of a metabolic intermediate
Of the carrier moiety or a metabolite thereof?
Gain in therapeutic benefit
Prodrugs of marketed drugs (post hoc design); modest to marked benefit
Prodrugs of difficult candidates (ad hoc design); marked to significant benefit

number of studies have proposed and investigated prodrugs activated by a purely or predominantly nonenzymatic mechanism. Prodrug of this type include:

- (2-oxo-1,3-dioxol-4-yl)methyl esters
- Mannich bases
- oxazolidines
- esters with a basic side chain sterically able to catalyze intramolecular hydrolysis

**Fig. 2** General reaction scheme for the intramolecular activation of prodrugs by cyclization–elimination. (Modified from Ref. 11.)

- esters and amides undergoing intramolecular nucleophilic cyclization–elimination.

Here, we focus on prodrug activation by intramolecular cyclization–elimination (8, 11). These reactions occur in specifically designed prodrugs of phenols, alcohols, and amines. A number of design strategies exist to achieve such mechanisms, as illustrated below with selected examples. The general chemical principle of these reactions is shown in Fig. 2. In such a schematic representation, the carrier moiety is a side chain attached to the drug by a carbonyl group (i.e., by an ester or amide function) and containing a nucleophilic group symbolized by “Nu.” The latter directly attacks the carbonyl in a reaction of nucleophilic substitution whose outcome is cyclization of the carrier moiety and elimination of the drug molecule.

Cyclization–Elimination Due to a Basic Amino Group

Nucleophilic attack by a basic amino group has proven to be a useful strategy to achieve and modulate cyclization–elimination. The radiation sensitizer

**Fig. 3** Activation of basic ester prodrugs of 5-bromo-2'-deoxyuridine by cyclization of the promoiety. (Modified from Ref. 12.)

Fig. 4 Activation of basic carbamates of phenols by cyclization–elimination of the promoity. (From Ref. 13.)

5-bromo-2'-deoxyuridine was derivatized with diamino acids to obtain the prodrugs shown in Fig. 3, with $R = H$ or cyclohexyl (12). The reaction of cyclization proceeded cleanly to yield the drug and a piperazinone derivative without any other detectable product being formed. No hydrolysis was seen in acidic solutions. At pH 7.4 and 37°C in a buffer solution, the half-life for the two prodrugs was 23 and 30 min, respectively. In human plasma under the same conditions, the values were 70 and 47 min, respectively, suggesting protection from breakdown by binding to proteins. In rat plasma, the half-life of the first compound was 47 min, again suggesting protection, but it was 5 min for the second compound. This is an indication that enzymatic hydrolysis by rat plasma hydrolases is possible in some cases.

Thus, intramolecular activation by cyclization–elimination was modulated by steric factors. In addition, this example shows that hydrolysis may be catalyzed by enzymes depending on substrates and biological conditions.

Valuable insights can be found in an informative study on the reactivity of phenyl carbamates of ethylenediamines (Fig. 4) (13). Their half-lives of chemical activation at pH 7.4 and 37°C showed that N,N' -dimethyl and N,N',N' -trimethyl substitution gave the fastest rates of cyclization, whereas N - H , N' - H , and/or N -ethyl groups markedly decelerated the reaction. The other major interest of this study is the proof it reported that no enzymatic hydrolysis occurred. Indeed, these compounds were incubated with human plasma, pig liver homogenates, and rat liver homogenates, the half-lives of release of

Fig. 5 Simplified reaction mechanism of intramolecular cyclization–elimination of phenyl carbamates of anthranilamides. (From Ref. 14.)

Fig. 6 Activation of hemiester prodrugs of phenols by proton-catalyzed hydrolysis (reaction a), hydroxyl-catalyzed hydrolysis (reaction b), or cyclization–elimination (reaction c). Enzymatic hydrolysis is not represented. (Adapted from Ref. 15.)

phenol being either identical to those in buffer, or slightly larger, because of protein binding.

Cyclization–Elimination Due to an Acidic Amido Group

In addition to attack by a basic nitrogen, there exists also the possibility of an intramolecular attack by an anionic nitrogen, i.e., a deprotonated amido nitrogen. This is exemplified by *N*-(2-carbamoylphenyl)carbamates of model phenols (Fig. 5; X = H, Cl, or OCH₃) (14). In such promoieties, the deprotonated carboxamido group attacks the carbamate carbonyl to form a quinazolinone and release the phenol. The stability of a large series of *N*-(2-carbamoylphenyl)carbamates was explored in buffer solutions and in diluted human plasma. The rate of nonenzymatic cyclization–elimination was highly sensitive to the nature of the carboxamido substituent (R' in Fig. 5). An alkyl substituent larger than methyl strongly decreased reactivity, presumably by steric hindrance. In contrast, an electron-withdrawing

substituent increased reactivity by facilitating deprotonation. Globally, these effects were significant because the rates span four orders of magnitude.

In human plasma, two groups of compounds were seen. In most cases, the reaction in plasma (i.e., chemical plus enzymatic activation) was approximately two-fold faster than in buffer. This indicates that enzymatic hydrolysis in human plasma, if any, was modest at best. Only for the three prodrugs with an unsubstituted carboxamido group (R' = H) was the enzymatic reaction several-fold faster than was intramolecular catalysis, suggesting these compounds to be substrates of plasmatic hydrolases. Thus, the *N*-(2-carbamoylphenyl)carbamate promoiety allowed a highly modulatable intramolecular activation with little enzymatic activation.

Cyclization–Elimination Owing to a Carboxylate or Hydroxyl Group

Intramolecular cyclizations are not restricted to attack by a nucleophilic nitrogen (basic amino or acidic amido group).

Fig. 7 Cyclization of *N*-2-hydroxyphenyl carbamates as potential prodrugs of benzoxazoles and phenols. (From Ref. 16.)

Table 3 Specific difficulties in prodrug design and development

Objectives	Strategy	Restrictive conditions
Minimize the number of proposed candidates	Careful prodrug design based on prediction of target phys-chem and PK properties	Available
Maximize the explored space of phys-chem and PK properties		Local quantitative models Global qualitative models (e.g., “rule of 5”)Dubious Global quantitative models
Minimize the additional synthetic work		
Reach target phys-chem profile	Careful weighing of costs and benefits	Limited acceptance of additional costs and efforts
Reach target PK profile	HTP phys-chem profiling Virtual screening	Limited or dubious relevance of some HTP techniques Dubious predictive capacity of some models (see above)
Reach target metabolic behavior, in particular target rate of activation	HTP PK profiling Virtual screening	Limited or dubious in vivo relevance of some HTP screens Dubious predictive capacity of some models (see above)
Lack of toxicity of prodrug, promoiety or fragment thereof	Fast in vitro metabolic assessment	Dubious extrapolation to in vivo situation
	Knowledge-based design Toxicity screens	Incomplete knowledge Limited or dubious in vivo relevance of screens

HTP = high throughput; phys-chem = physicochemical; PK = pharmacokinetic.

They can also be catalyzed by a nucleophilic oxygen as found in a carboxylate, phenolic, or alcoholic group. Illustration of the catalytic role of a carboxylate group can be found in hemiester prodrugs of phenol (taken as model compound) or paracetamol (Fig. 6; R = H or NHCOCH_3 , respectively) (15). In addition to enzymatic hydrolysis, three mechanisms of chemical hydrolysis were seen, namely, acid-catalyzed, base-catalyzed, and an intramolecular nucleophilic attack, resulting in cyclization–elimination (Fig. 6, reactions a, b, and c, respectively). In buffer solutions, the relative importance of these three pathways was clearly pH-dependent. At physiological pH, cyclization–elimination was the predominant reaction, with half-lives ranging from 1 to 350 min at 37°C. Reactivity at this pH was markedly influenced by the length and degree of substitution of the promoiety and by the pK_a value of the phenol. Thus, succinate esters (Fig. 6; X = CH_2CH_2) were approximately 150 times more reactive than were glutarate esters (X = $\text{CH}_2\text{CH}_2\text{CH}_2$); C-methylation of the promoiety (X = $\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2$) also increased reactivity. Esters of paracetamol (R = NHCOCH_3) were degraded about twice as fast as were esters of phenol (R = H).

In most cases, the hemiesters in Fig. 6 underwent no or little enzymatic degradation in human plasma, in agreement with the known inertness of hemiesters toward cholinesterase. In contrast, very rapid hydrolysis was usually seen in pig and rat liver preparations, indicating the involvement of carboxylesterases. The only inert compound was the 3,3-dimethylglutarate hemiester of paracetamol (Fig. 6; X = $\text{CH}_2\text{C}(\text{CH}_3)_2\text{CH}_2$). It certainly would be interesting to have data on the hydrolysis of such prodrugs by human hepatic enzymes.

The hydroxyl functionality in phenols and alcohols is also of potential interest as an intramolecular nucleophile. One example of this type is presented here (16). *N*-2-hydroxyphenyl carbamates (Fig. 7) undergo intramolecular cyclization with quantitative liberation of a phenol or an alcohol. The interest of this approach is that the product of cyclization is itself a drug, namely, the skeletal muscle relaxant chlorzoxazone. A large variety of phenols and alcohols were investigated in this work, most of them model compounds, but paracetamol was among them. In this case, a prodrug of this type liberates not one but two drugs and can be called a mutual prodrug.

The mechanism of activation in Fig. 7 was demonstrated to be an intramolecular nucleophilic attack by the phenolate ion on the carbonyl group. As a consequence, the rate of reaction increased linearly with pH, up to a plateau at 8–9 and beyond. The major factor influencing the rate of reaction was the acidity of the leaving ROH molecule, with $t_{1/2}$ values at pH 10 and 25°C ranging from

290 days for ROH = $\text{CH}_3\text{CH}_2\text{OH}$ (pK_a 16.0) to 3–12 s for ROH = phenols of pK_a 9–10. The $t_{1/2}$ value for ROH = paracetamol was 7.1 s at pH 7.4 and 37°C (16). Some prodrugs and mutual prodrugs in Fig. 7 were also examined for their stability in human and rat plasma (16). These *N*-2-hydroxyphenyl carbamates showed two- to threefold increases in $t_{1/2}$ values in human and rat plasma compared with buffer. This indicates the absence of an enzymatic hydrolysis and a modest stabilization owing to binding to plasma proteins.

SOME PROBLEMS IN PRODRUG RESEARCH

The benefit brought forth by a prodrug relative to the active agent is worth considering. Schematically, it appears from innumerable data in the literature that the gain will be considerable when the development of an innovative and very promising agent is blocked by a major pharmacokinetic or pharmaceutical defect that a prodrug strategy can overcome. In contrast, the gain will be negligible when the drug defect is tolerable or barely improved by transformation to a prodrug. But what of the specific difficulties encountered in designing and developing prodrugs? Table 3 schematically presents some of these difficulties (17), to which one can add possible complications in registration.

Thus, it's no wonder so many medicinal chemists are critical of prodrugs. However, and this is our conclusion, a lucid view cannot ignore the potential benefit, in this case the mere existence of a number of successful prodrugs. Nabumetone, oseltamivir, and pivampicilline are just a few examples that come to mind. They demonstrate that in a number of cases, prodrug design may indeed allow the separate optimization of PK and PD properties.

PROJECT MANAGEMENT

Jerry J. Groens

Covance Central Laboratory Services, Inc., Indianapolis, Indiana, U.S.A.

INTRODUCTION

New products are developed and introduced in organizations primarily through the use of projects and teams. Research of new technologies and innovation is essentially accomplished through the use of projects as well. The processes for developing and introducing new products are certainly more structured and well understood when compared with research; however, the essence of each is that they are projects.

A project is a *temporary endeavor undertaken to create a unique product or service* (1). Project management provides the processes, tools, techniques, skills, and knowledge needed to manage a project such that the results meet or exceed the stakeholder needs and expectations. Stakeholders are the individuals or organizations whose interests may be positively or negatively impacted by the project.

Searching for sources of project management in the literature, an individual finds hundreds of books, articles, and cases covering the topic in all industries, environments, and situations. These sources emphasize that every project is different and that projects exist in an environment of change, uncertainty, and inconsistency. However, some of these sources then proceed to state that “project management is a science” and that the processes of project management are consistent across all industries and environments. Any successful practitioner in project management in the fields of product development and, more specifically pharmaceutical development, knows that this is not correct. Project management is more, much more of an art than a science, and the application of project management is not consistent across industries, environments, and situations.

For example, many of the elements of project management applied in the construction and telecommunications industries do not work in pharmaceutical development. This includes earned value, configuration management, and detailed representations of the work breakdown structures. These concepts actually provide too much structure when applied to pharmaceutical or any product development and

could potentially have a negative impact on innovation, creativity, and effective teaming. Therefore, the creation of a development framework, based upon the principles and practices of project management, is required to address the uncertain world of pharmaceutical development. This chapter will focus on that framework.

A PROJECT MANAGEMENT FRAMEWORK

A project management framework has six elements. These are:

- Project definition,
- Project team and organization,
- Project planning, scheduling, and control,
- Problem solving and decision making using prototypes,
- Senior management review and control, and
- Proactive, real-time change management (2).

Each of these items is key to the successful management of a new product development project. For example, the project definition processes develop:

- The project scope and objectives,
- The business case and the technologies utilized,
- The project strategy or direction being pursued,
- The sponsorship and championship for the new product
- Concept, and
- The final product performance targets and deliverables.

This project management chapter will cover each of these elements of a project management framework and provide sources for further study.

PROJECT DEFINITION

This first element of a project management framework is used to define project scope and objectives. It outlines what is within and not within the project boundaries,

the business case and market need, the technologies to be used to solve that business case, and the initiation, selling, and sponsoring of the project.

The scope of the project includes not only the definition of the final product deliverable but the level of work effort required to complete this project. For example, a new pharmaceutical drug will be used to reduce long-term intractable pain, will be in an injectable form, and will use existing packaging configurations in defined concentrations and formulations. This is an initial, general definition of the product scope. The project scope, however, is much more time consuming and complex to develop and would include:

- The number, type, and cost of clinical studies or trials (including number of patients and sites) required in each phase of development to complete the project;
- The formulation, analytical chemistry, packaging and sterilization/microbiological work needed; and
- The manufacturing processes, equipment, and other resources required to produce the product.

Resource estimates (hours and dollars) for people's time, expenses, and capital are projected along with an approximation of the timing of the need for these resources. This becomes the basis for a project approval document or *charter*, which also includes the product scope, project objectives, business case, and financial evaluation.

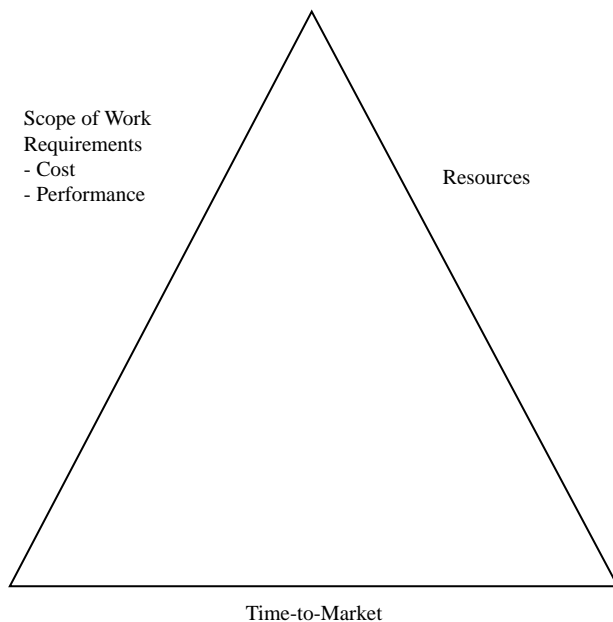

Fig. 1 New product projects objectives. (Adapted from Ref. 3.)

Project objectives are also a key element of project definition and set the direction for a product development project. These objectives operate in an environment where trade-offs are necessary, and are often referred to as the *triple constraint* (see Fig. 1). Looking at these three constraints, a few questions may come to mind. For example:

- How often have you been on a project where the scope did not change? Probably never, and if you have, this is very unusual.
- How often have you been able to estimate the original resources required on a new project as closely as $\pm 5\%$? Probably never, and if you have, this is very unusual.
- How often are you allowed as much time as needed to complete the project? Probably never and, in fact, cycle time reductions are the norm.

Given these experiences, and assuming that these are typical and true, a project manager recognizes the magnitude of the challenges in being successful because meeting these objectives is the measurement of success. This emphasizes the relevance of an old phrase that many project managers quote from time to time: “fast, cheap, or good; pick two.” This may be a catchy phrase, but it highlights a crucial dilemma in project management. To help solve this dilemma, the project manager needs to understand the expectations of the sponsor and key stakeholders and to periodically assess them throughout the project life cycle. The project manager may identify some “give” or slack on one and possibly more of these expectations depending on the project, with its unique uncertainties and challenges. In the pain management example, most likely a specific target level of pain reduction is crucial to successfully achieve the product (product performance) requirements. This will probably represent the area where changes in project scope and direction will most likely occur. Since getting the product to market quickly is a goal (time-to-market), providing sufficient funding (resources) to support these objectives is critical. So, where is the “give” in the objectives based upon the needs of the management stakeholders? Managing the triple constraint and the expectations of management with regards to these objectives requires the development and management of the project's business case with financials.

The business case for a new product project should include the following:

- An evaluation of the market and customer needs including appropriate market research studies,
- An analysis of the competition including their potential products and strengths and weaknesses,

- A technical assessment of the capability of the organization as it relates to the product competing in the market,
- A statement of alignment to the organization's business strategy, and
- A preliminary evaluation of the financial opportunity of the new product, which may include use of return on investment, discounted cash flow and internal rate of return, net present value, and break-even time (4).

Due to the uncertainty involved in the evaluation of new products, financial analysis tools that consider risks and opportunities are more appropriate and valuable than deterministic approaches. These new approaches to project financial evaluation that consider uncertainty include options analysis and Monte Carlo simulation. Due to their proactive handling of uncertainty, these tools can more accurately calculate the risks and opportunities of a new product concept (5). With the use of a financial analysis model, basic trade-off statements can be developed by the project manager to assist in understanding the importance of each objective. In the pain management product example, a statement emphasizing the value of time would be "a week delay in the project costs \$1 million in today's money" (6).

Of course, all of this project definition process and effort, hopefully, will lead to an approved and ultimately successful new pharmaceutical product. The need for a concurrent process of project selling and support is emphasized due to the nature of new product development, the uncertainty of the projects, high cost, and limited resources. To accomplish this task, a new product project requires two types of individuals early in its life cycle:

champions and sponsors. Project champions are individuals within the organization who support the project and sell it to management. Project sponsors are senior-level executives whose support is needed to fund and provide resources for the project. Of course, the more champions that a new product has selling the concept, the greater the potential for funding and support from senior-level executives. The level of support needed and number of senior executives increases as the funding requirements of the project increase. This is probably obvious, and yet not recognizing them can result in missing a key new product concept.

Early in the life of a new product, its future is tenuous and requires an approach that not only puts it through a rigorous business, technical, and financial evaluation but allows it to nurture and grow into a development project where appropriate. An organization should have an early new product process that: 1) captures and provides an opportunity for all the valuable new concepts that an organization is researching to be evaluated on a level playing field, and 2) focuses the organization on those key few projects that allow for fast product development. This concept, called the "funnel" (Fig. 2) in some sources (2), shows the need for the following elements of successful initial project definition:

- A proactive process of mining both externally and internally for new product concepts,
- Research for these new product concepts and funding for the same to assure that the concepts are developed to an appropriate level prior to evaluation, and
- A process to evaluate new product concepts to assure that the best concepts are fully funded based upon the criteria identified above under business case.

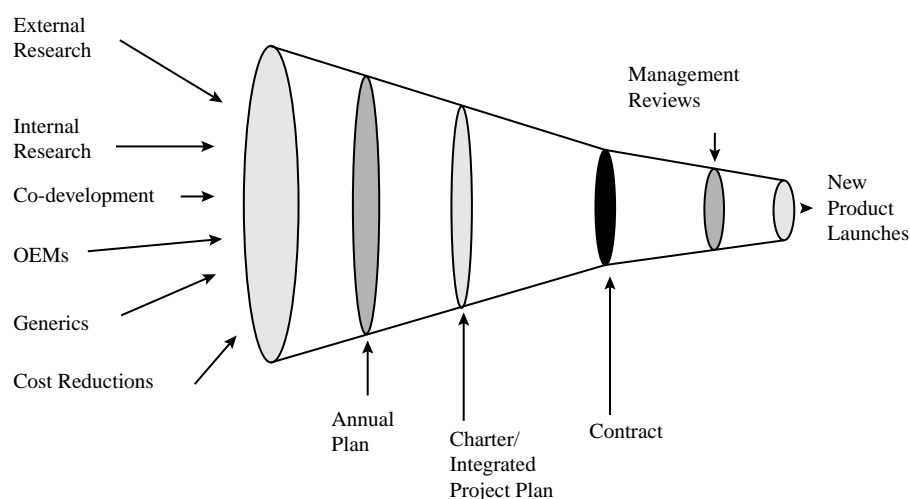

Fig. 2 New product "funnel."

The evaluation process, sometimes known as “stage gates” and “phased reviews”(7), needs to be accomplished early in the development project life and continue on throughout the life of a project as needed and defined in a *contract or integrated project plan*. The project plan will be reviewed later in this chapter along with its use in project reviews and stage gates.

PROJECT TEAM AND ORGANIZATION

A team is a small number of people with complementary skills who are committed to a common purpose, performance goals, and approach for which they hold themselves mutually accountable (8). Teams, however, are not necessarily the answer to all business endeavors, but the challenges of new pharmaceutical drug development lends itself very well to this organizational approach.

“Core” or primary team and support teams are used often to keep the number of team members small. A graphical illustration of this type of core and support team is shown in Fig. 3. Core team members represent the different functions of an organization, have significant authority and responsibility in the organization (especially for high priority projects), and have both specialist/technical and generalist/business skills. In the pain management example, the core team may include team members from:

- Program management,
- Marketing management,
- Clinical development,
- Formulation development,
- Analytical chemistry,
- Process development,
- Operations management, and
- Regulatory management.

Fig. 3 Design of a project team.

This team example meets the definition criteria in that it is small in number and contains team members that have complementary skills and represent all or most of the functions in the project. Support teams and support team members would then be set up to work on the major elements of the project. In the graphical illustration shown in Fig. 3, these support teams would work on formulation development, clinical development, market introduction, and manufacturing process development.

To be small and effective, a core team should have around twelve members. For major, high-priority projects each team member must have considerable authority and responsibility within their respective functional organization. Each team member

- Ensures functional expertise on the project,
- Represents functional perspective on the project,
- Ensures functional deliverables are met, and
- Proactively raises functional issues that impact the team (2).

This “heavyweight” team member has the authority to either make the decisions and solve the problems on their own or involve the right functional support for decision making and problem solving.

Team members also represent the team. “Heavyweight” team members

- Share responsibility for team results,
- Revise project tasks and content,
- Establish project status reporting and other organizational responsibilities,
- Participate in monitoring and improving team performance,
- Share responsibility for ensuring effective team processes,
- examine issues from an executive point of view, and
- Understand, recognize, and responsibly challenge the boundaries of the project and team processes (2).

Team members must realize that they are part of a team. For the team to be most productive and effective, team members must collaborate with other team members, put aside their own personal or functional agenda, and use dialogue (10, 11) to develop a common understanding and create the best cross-functional approach for the project and the organization.

The term “heavyweight” has been used in this section to designate team members with significant authority and responsibility. Essentially, a heavyweight team is one where more decision making and problem-solving authority and responsibility reside in the team rather than in the functions. As shown in Fig. 4, teams need both a functional or specialist perspective and a project or

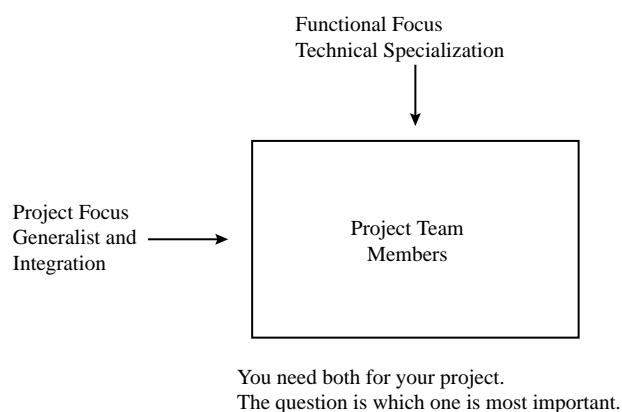

Fig. 4 Project organization structures.

generalist perspective to be effective. Depending on the needs of the project, either the functional or project perspective will be more important to its success. For example, a research project requires more of a technical specialization than a generalist perspective to be successful. Consequently, a functional approach would be more appropriate. Also, a small, generic drug project may not require the team clout and generalist perspective that a larger, proprietary drug would require. Consequently, a “lightweight” team, one where the functional perspective is more important and decisions are made mainly within the functions, may be more appropriate. A “heavyweight” team would have a stronger team oriented, cross-functional perspective rather than a functional perspective. A project or venture team, one where the team members are removed from their functions to report directly to the project leader, may be appropriate in some proprietary drug projects. Such a “heavyweight” team should be created in situations where a new business or market is being entered (12).

Leading a “heavyweight” team requires a project manager who has significant authority, responsibility, and skills, both technical and generalist, to be successful. A “heavyweight” project manager is one who manages, leads, and evaluates other members of the core team, champions the core concept, manages “in motion,” is a multilingual translator (being fluent in different functional languages), and provides direct interpretation of market and customer needs. These individuals “earn the respect and right to carry out these roles based on prior experience, carefully developed skills, and status earned over time. A qualified leader who can play those roles as a heavyweight project manager is a prerequisite to an effective heavyweight team structure (2).

For an effective and productive team-oriented structure, organizations must support cross-functional

teams and use these teams in a way that makes them more effective. Support of teams requires teams be recognized formally as the approach for developing and introducing new pharmaceutical drugs to market. This may sound obvious, but in practice this requires new approaches to

- Performance appraisal—including team-member and total team results with functional evaluations,
- Promotion and pay—creating incentives based upon team results and involvement in successful new product teams, and
- Career development—providing lateral career paths across the functions that develop heavyweight team members.

Anything less than changing the core approaches to these items will result in a team environment that is less than optimal (13).

PROJECT PLANNING, SCHEDULING, AND CONTROL

Although project management was certainly applied in practice prior to the mid-1950’s, the development of the critical path method and the Project Evaluation and Review Technique (PERT) is considered to be the initiation of the modern practice of project management. The critical path method is a network analysis technique used to predict project duration by analyzing which sequence of activities or path most likely has the least amount of scheduling flexibility or the least amount of float. This critical path determines the earliest completion of the project (1). The critical path method relies on one estimate for the duration of a task, whereas PERT uses three estimates. These are most likely (i.e., the critical path method), worst case, and best case estimates. In practice, PERT becomes a very cumbersome approach to scheduling and tracking time.

Network logic determines the relationship between the tasks or team member deliverables, either sequential (finish to start) or overlapping (start to start and/or finish to finish). There are numerous software packages available at low cost to support calculation of the critical path and float. However, the real challenge of project management tools is the creation of the project network based upon historical experience and team involvement. By definition projects are unique and, in the pharmaceutical arena, each project is different. Therefore, the importance of team member involvement in the development, tracking, and adjustment of the project schedule is crucial to successful application of project management basics.

A popular approach for team members to develop a project network diagram is a concept known as the “yellow sticky” method. This method uses post-it notes, roll-paper, and markers and the team to develop a network diagram. The suggested steps of the “yellow sticky” method are as follows:

1. Identify the milestones that the project team will track with management along with target completion dates.
2. Identify the team member deliverables or responsibilities that need to be completed prior to the milestone dates (this provides ending linkages for deliverables).
3. Create the network diagram as follows:
 - Identify which tasks can be started today, based on availability of information not upon availability of resources.
 - Identify which tasks can be started after the initial tasks are completed, which tasks can be completed after that and so forth to the end of the project or the next major milestone.
4. Obtain team member commitments to deliverables—usually best accomplished after the first planning meeting.
5. Negotiate between project milestone dates and team member deliverable dates.

Step 2 uses a very valuable tool known in project management as the work breakdown structure. The work breakdown structure is a “deliverable-oriented grouping of project elements which organizes and defines the total scope of the project” (1). In this example, recommended for pharmaceutical development use, the project is organized at the first level by the milestones that will be tracked. These are the milestones that senior management wants to see in the project. Examples are FDA submission, IND submission, product first lot to stock, first clinical supplies produced, etc. Under the milestones, each team member has deliverables, which are “any measurable, tangible, verifiable outcome, result or item that must be produced to complete a project or part of project” (1). Example of team member deliverables would be to develop the analytical method, develop the product formulation, develop the sterilization process, develop the manufacturing process, develop the specifications, produce clinical supplies, develop the clinical program, and prepare regulatory submissions. Project planning at a level of detail below this can certainly be done. However, a good rule of thumb is to plan down to the level of detail where a team member accepts primary responsibility for the deliverable and no further, unless two things happen:

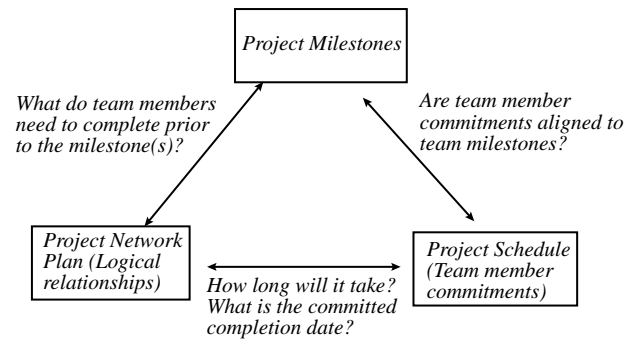

Fig. 5 Team-based project planning and scheduling approach.

- A team member does not understand the job and/or
- A team member is not motivated to do the job.

Standard operating procedures should handle the first issue and having the right team members should handle the second issue. Planning in more detail than this will result in unmotivated team members (i.e., micromanagement) and a schedule that is too cumbersome and detailed for tracking.

Steps 1–3 of this planning method are best accomplished in a core team meeting, along with support team members. Steps 4 and 5 are best accomplished after the meeting when the team members have time to evaluate their workload and commit to the deliverables. Negotiating the deliverable dates with project milestones is also best accomplished after the meeting. Project team members should be advised of the status of this process, but the project manager needs to accomplish this with individual team members, parts of the project team and management, and/or external stakeholder groups. This part of the process is graphically shown in Fig. 5. If there is a misalignment between management’s expectations for completion of major milestones, there are a number of options:

- Change the milestone date,
- “Fast track” the project schedule, or
- “Crash” the project.

Changing the milestone date is straightforward. The target date is rescheduled because the original assumptions for this date were proven to be incorrect when the team came together to schedule the project. “Fast tracking” the project means to compress the project schedule by overlapping activities that would normally be done in sequence. This requires some risk taking, which needs to be clarified. “Crashing” the project means to decrease the total project duration after analyzing a number of alternatives to determine how to get the maximum duration compression for the least cost.

“Crashing” usually occurs by adding resources to reduce time. This happens when additional resources will not significantly reduce the time because the additional resources are not knowledgeable about the technology or part of the team process or a particular task requires a set period of time to complete.

The result of the project planning and scheduling process should be a planning document often called the project or integrated project plan. This serves to emphasize that it represents the integrated plan of all the team members. An integrated project plan should include the following information:

- The project scope and objectives,
- The business case and financial analysis and model of the project,
- The project risks and issues with contingency plans,
- The project plan and schedule (in milestone form for management review and in detailed team member deliverable form for the team members),
- The roles and responsibilities of the team members (best represented through a work breakdown structure tied to project milestones),
- Functional and technical strategies (e.g., regulatory strategy, plans, and challenges), and
- Performance measurements and incentives.

This is meant as an example for illustrative purposes, and the project manager and team should develop their own format and outline based upon their needs.

The Achilles’ heel of project management is the time and resource estimate. In the majority of cases these are actually wrong. The only question is the level of inaccuracy in the estimate. There is no real scientific approach to better estimates and, similarly with all forecasts, it is more of an art and a “feel” to estimating than a science. Consequently, due to the uncertainty of projects

Fig. 6 Time and resource estimates: The Achilles’ heel of project management.

and estimates, it is best to try to work with two numbers: the most likely and the high number (see Fig. 6). New, workable (as opposed to PERT) approaches to project management (i.e. “critical chain” project management) are available to schedule around uncertainty (14).

Once a project schedule is complete, it is used to track and review project progress towards completion. Some basic concepts on this are as follows:

- Project controls need to start with the team members.
- Team members need to take ownership for their tasks and part of this ownership is communicating status on a timely basis.
- A hierarchy of project reviews is needed in support of a pharmaceutical development project. Starting with project core and support team reviews on a weekly or more often basis, project reviews with management and other stakeholders are important to having a common understanding of project status.

Each of these elements would be part of a communication plan to be reviewed in a future section.

PROBLEM SOLVING AND DECISION MAKING USING PROTOTYPES

Pharmaceutical development projects consist of phases, technology transfer processes, milestones, and problem-solving cycles. Understanding these basic building blocks of pharmaceutical development projects in general and more specifically for your project is important towards understanding how your project will progress and how to structure that progress for status and communication purposes. For example,

- The phases of clinical development for a pharmaceutical development project: phase I, II, III, IV and post-marketing;
- The technology transfer from research to development and from development to manufacturing;
- The major milestones of a pharmaceutical project: FDA submission and first lot to stock;
- The use of different product prototyping cycles and their value towards solving problems, communicating results, and making progress.

An example of a pharmaceutical development life cycle is shown graphically in Fig. 7.

The transfer of technology from one organization to another is a key phase of the project itself. As shown in Fig. 8, there are two different approaches that can be used in the transfer of technology:

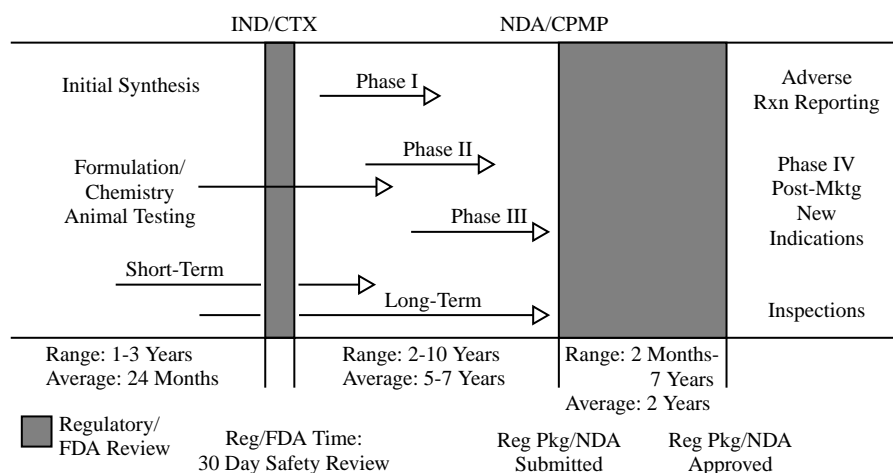

Fig. 7 Drug development phases.

- The traditional, sequential approach or
- The overlapping, concurrent approach.

The sequential approach is often known as the “throw it over the wall” approach. In this approach, the upstream group (e.g., the development team) waits until the product development effort is complete and creates specifications for the new product before communicating this information to the downstream group (e.g., the manufacturing team). Traditionally, this approach has been popular because it gives the perception of being efficient, that is, no time is wasted on incomplete designs and development work. Most often, however, this results in significant rework and inefficient use of time.

The overlapping approach is the more effective and efficient approach in practice and results in a truly integrated transfer of technology. In this approach, both

the upstream and downstream groups work together to understand and solve the problems that need to be resolved to transfer the technology. Examples of these problems may include

- Development and transfer of the analytical methods.
- Development and transfer of the solution process.
- Development of product packaging, and
- Development of sterilization steps and methodology.

In an overlapping approach, team members from both the upstream and downstream groups work together to accomplish these tasks, resolve the problems, and make the necessary decisions. This requires early and intense involvement of the downstream group, even at times when it appears that progress is not occurring. This also requires early sharing of incomplete and, at times, inaccurate information by the upstream group. Sharing of this information may be considered risky due to the uncertainty of response from the downstream group. This approach requires collaboration and trust between the two groups—two basic elements to successful product development and teams (2).

Another basic building block of any product development project are design–build–test cycles. These cycles use prototypes to serve as a focal point for problem solving, testing, communication, and conflict resolution. Using these cycles provides feedback on decisions made so far and identifies issues that need to be resolved. Examples of the prototyping cycles for a clinical development project are

- Identify the bulk drug vendor,
- Determine formulation feasibility,
- Complete engineering runs,

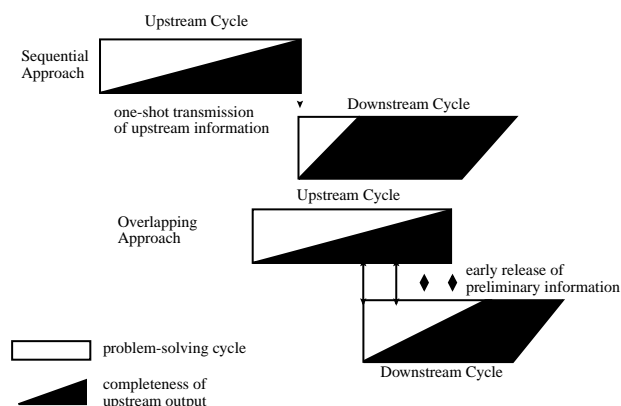

Fig. 8 Cross-functional integration requires overlapping problem solving. (Adapted from Ref. 9.)

- Produce clinical and/or stability samples,
- Ramp-up manufacturing process, and
- Produce first lot to stock product for sale.

These examples are shown to illustrate the importance of the design–build–test cycle process. Cycles will vary from project to project. Completing each of these cycles is a very effective approach to tracking and demonstrating project progress. Prototypes can provide very focused communication about the progress to date and the remaining tasks required to complete the project (2).

SENIOR MANAGEMENT REVIEW AND CONTROL

Senior management provides the sponsorship, championship, and funding for the pharmaceutical development projects that new product teams are working on. They need to be involved and understand the importance of the project, its link to business strategy and growth, the risks and issues that the project is facing, and the status of the project. This understanding is important throughout the life of a project particularly at the start of the project. As shown in Fig. 9, the opportunity to effectively impact the project direction and scope is greater at the start of the project. However, as the project progresses, it becomes more difficult and costly to impact the project direction and scope. Typically, senior management involvement increases as the project gets closer to providing return on investment. This is usually late in the project life cycle and due primarily to an increase in project visibility as sales and marketing activities intensify.

Senior management involvement, especially at the start of the project, is key to successful project outcomes. Some

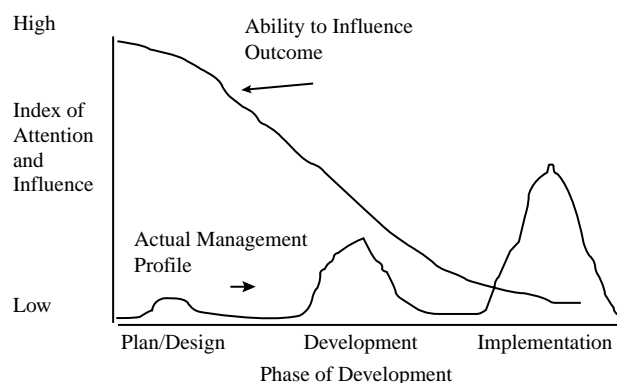

Fig. 9 Obtain senior management involvement early in setting projects direction. (Adapted from Ref. 15.)

process guidelines to assure management involvement are as follows:

1. Senior management should define strategic direction that will be used to drive new product development.
2. Senior management should define the new product project portfolio and the aggregate set of projects that will achieve their strategic objectives.
3. Senior management should be actively involved in assigning the type of project team (see earlier section) and type of project, i.e., where this project falls in the portfolio.
4. Senior management should develop and support a project review process that encourages early involvement in the project to validate the business assumptions and decrease project surprises (12).

The project manager of a pharmaceutical development project should proactively drive these process elements to assure active and early involvement of senior management in their project. The project must have the right support and visibility. Additionally, these process mechanisms assist in timely and appropriate project discontinuations.

Project reviews with senior management are a key element of the new product process. The project manager should have the ability to interface directly with senior management. As previously mentioned, a hierarchy of reviews is important to assure timely, continual communication of project status and issues. Also, stage gate reviews are a very popular process for clarifying project definition and evaluating the project's business case and technical issues. Senior management should get involved in these reviews to assure that the project continues to be on target and meet the overall goals for new product development. Senior management reviews should evaluate

- The business issues and goals of the project,
- Issues related to the customer's needs and the marketplace;
- Resource management;
- Corporate and business unit direction and product line fit;
- Sales and payback expectations;
- Project schedule;
- Timely introduction to market, and
- The availability and maturity of the technology to meet quality and cost targets;

These reviews can be scheduled to occur on a regular basis (e.g., after a phase is completed or every quarter, as stage or phase gates propose) or on an as-needed basis by senior management or the project team. The timing will be dependent upon the organization's requirements and the

specifics of the project. These reviews can be mandatory (i.e., project can not proceed until this review is completed) or flexible. This is dependent upon organization's requirements and the specifics of the project. In all instances, these reviews need to be used to determine whether or not to continue with the project (e.g., make go/no go decisions) or change project direction (e.g., scope change). The concept of scope change will be the topic of the last section of this article.

PROACTIVE, REAL TIME CHANGE MANAGEMENT

As mentioned in this chapter previously, scope changes are to be expected in a pharmaceutical development project. The only question is the number and severity of these scope changes. Consequently, projects need a process for managing scope changes. Mandating the same, centralized controls for all projects, however, would probably be too constricting and result in unneeded bureaucracy—perhaps even impacting the ability for the project to be successful. The project team needs to self-regulate; manage scope changes depending on the unique needs of each project; and have the discipline to ensure appropriate process controls and management review.

Managing scope changes requires the proactive installation of a scope change process for projects that includes a method for identification and management of project risks. A suggested process for managing scope changes is the following:

1. *State the real problem*—Why is this scope change needed? It has been suggested to categorize scope changes into types to assist in determining the relative necessity and importance. Again, this may be overkill.
2. *Gather the relevant facts*—What is the impact if the scope change is implemented? What is the impact on the time to market and effect on development and final product costs? What will happen if the scope change is not implemented? These facts should be obtained from the appropriate people (i.e., the stakeholders that will be impacted one way or another by this scope change).
3. *Develop several alternative solutions*—Should nothing be done? Implement the total scope change as requested? Is there a compromise solution? Which stakeholders are interested in each solution and what are their expectations?
4. *Analyze and review impact for alternatives*—What are the impacts on time to market, investment cost, and product cost for each alternative? Financial analysis is a key element of this step because senior management

uses financials as a critical business indicator. Therefore, each alternative needs to be evaluated versus a financial model. What are the risks and trade-offs to consider for each alternative?

5. *Adopt the best alternative*—This is the connection to the senior management review process. For major scope changes, the project manager should provide an analysis of the major solutions. Based upon financial analysis and qualitative factors, the project manager should present the project team's recommendation to key stakeholders and senior management for their agreement and support.
6. *Tell everyone*—Obviously, the project team should be advised of the change in project scope because they will need to implement it. Project stakeholders also need to be advised so that they can support the scope change with the appropriate resources.
7. *Audit the outcome*—This step is undervalued. The success or failure of a project often relies on how well a scope change was or was not implemented. There are lessons to be learned from capturing the events that led to and caused scope changes and whether the change had a positive or negative impact on project success (17).

As mentioned previously, financial analysis of scope changes and the development of alternative solutions are critical steps towards the successful implementation of a scope change. Senior management needs this information to understand the financial impact on the business and the project manager must provide it. A suggested approach is illustrated graphically in Fig. 10. This approach requires that the project manager use a financial model for the project (which all projects should have) and understand

- The cost/benefit of time delays or improvements;
- The financial impact of increased or reduced product cost and/or project investment; and
- The benefit of improved product use, indications, functionality, or features.

Outlining the relationship of each of these variables to the scope change is an important first step. For example, delaying the project by one week costs approximately \$5 million in division margin. A second step is to understand the specific impact of the scope change on each variable. For example, a scope change to add an additional product use and indication could delay the project three months (a 50% probability), cost an additional \$5 million to implement, and result in additional division margin of \$50 million over the life of the product. Is this worth the investment? Of course, the intangibles also need to be considered.

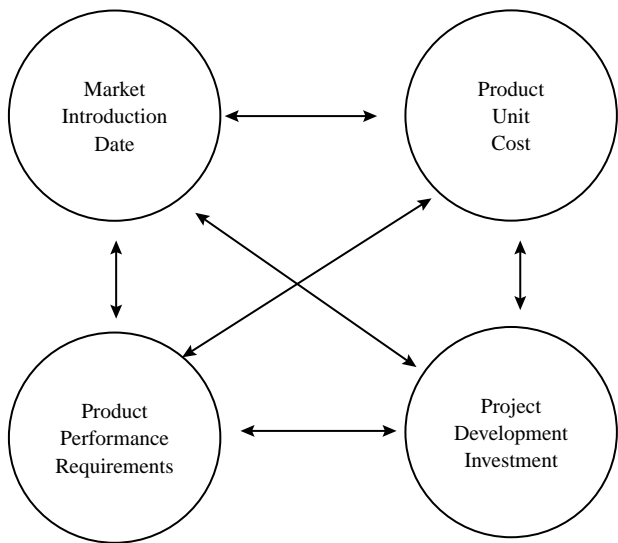

Fig. 10 Financial evaluation for justification of a scope change. (Adapted from Ref. 16.)

This “broad brush strokes” type of financial analysis is fundamental towards making informed decisions regarding trade-offs around the project objectives and scope changes (6). Given the magnitude of uncertainty of and complexity associated with pharmaceutical development, scope changes in this environment require more sophisticated analysis approaches (e.g., Monte Carlo simulation, options analysis, etc.). These tools are beyond the scope of this chapter, and the reader is asked to review the sources mentioned in the earlier sections of this chapter.

Uncertainty is reality in pharmaceutical development projects. Project uncertainty can be found in

- *The marketplace and the competitors:* What other companies will enter this market with a new drug and indication and what will be the impact?
- *The technology and its maturity:* Will our pharmaceutical and medical technology successfully solve the customer’s problem or, at the least, produce better customer outcomes? Will the customer understand and use this technology?
- *The regulatory and governmental environment:* Will the regulatory bodies and government agencies modify the rules? If so, will it affect the basic assumptions of the project? Is there impact on the development, approval, or marketing of the product?
- *The suppliers of bulk, unique commodities and services—*Can the suppliers deliver on the sub-objectives of the project? Are there risks related to their technology, capabilities, or governing environment?

- *The project internal risks (e.g., funding, schedule, team components):* Are the project team members capable of doing their tasks? Will the funding be available to support the project? Can the schedule be met?

These are general categories of risks and not meant to be all inclusive. Using these risk categories as a starting point, the project manager should expand on and flesh out specific details in order to define the most complete picture.

Risk identification is the first step of a risk management process. After risk identification, the project team needs to evaluate each risk in terms of two elements: 1) the probability of occurrence and 2) the financial impact. A popular tool in this process is a risk matrix shown graphically in Fig. 11. The matrix is used to identify the most important risks—those for which a contingency plan needs to be developed. The most important risks would fall into Quadrant IV of the matrix—those with a high probability of occurrence and high financial impact. As the example matrix indicates, the lines drawn between high and low is not quantitatively set but based upon the input of the project team. For risks in Quadrants II and III, continual monitoring is needed to determine whether the situation has changed significantly to warrant a contingency plan even though such a plan was not developed initially.

The basic concepts for risk management in a new product project environment are as follows:

1. Risk identification, quantification, and contingency planning is best accomplished with the full core team being involved.
2. Contingency plans will not be implemented for all risks that have been identified. However, when identifying risks, a common approach is to suggest a contingency plan for this risk. This can serve to encourage a proactive positive approach.

		Probability of Occurrence	
		Low	High
Financial Impact	High	Quadrant II Low Probability High Impact No Contingency Plan Monitor	Quadrant IV High Probability High Impact Develop Contingency Plan
	Low	Quadrant I Low Probability Low Impact No Contingency Plan	Quadrant III High Probability Low Impact No Contingency Plan Monitor

Fig. 11 Risk management plan.

3. Risk management is an ongoing process. You can't complete it and leave it. Many a project manager learned this hard way. Continual monitoring of risks, especially those in Quadrants II and III, is essential.
4. In general, risks resulting from project uncertainty are potentially the most damaging scope changes that could impact the project. It behooves the project manager and the team to proactively manage scope changes through a risk management process.

CONCLUSION

Traditional project management methodology (i.e., for the construction industry) developed 40 years ago has metamorphosed into an approach for managing new product development projects. This more flexible form of the application works well within a decentralized, team-oriented environment—an environment that is conducive to successful pharmaceutical new product development. Project management within the pharmaceutical arena plays a key role in bringing teams together, integrating solutions across functions, and providing a generalist view of projects to balance the more scientific/technical perspective. The future successful project manager will have a generalist orientation, hold team effectiveness and cross-functional integration as the top priority, and strive to overcome the barriers that would undermine these core tenets.

It is not enough to understand the concepts or utilize some of the tools of project management. For the most optimal results, organizations need to recognize the importance and fully support the role of project managers. Often organizations not fully committed to project management opt for interim or temporary solutions such as dual project leadership—a project having both a technical leader and a project manager. A similar tactic would be to have “dual hat” project managers—those who are project managers as a secondary role to their primary role as a functional or technical manager. These need to be replaced with a project manager performing solely that role and who will possess enough skills, knowledge, and

clout to get the project completed. This is not an easy solution, but organizations will find that the right solutions are not often the easy ones (18).

PROTEIN BINDING OF DRUGS

Sylvie Laganière

Origenix Technologies, Inc., Quebec, Canada

Iain J. McGilveray

McGilveray Pharmacon, Inc., Ottawa, Ontario, Canada

INTRODUCTION

When a drug reaches the systemic circulation, either after intravenous administration or after absorption following extravascular administration, it can be distributed in the elements of blood (erythrocytes, etc.) or bind to plasma proteins. Blood transports the drug to different organs where it diffuses at different rates. The drug not bound to plasma proteins will diffuse in the extravascular compartments and tissues where it can then bind to other proteins or other tissue components.

The free drug concentrations are more closely correlated to the desirable or undesirable (toxic) pharmacological responses of a drug, because it is the unbound drug that is available to reach tissue receptors (1–3). However, it is the total (bound + unbound) drug concentration, measured in plasma or blood that is most often used in therapeutic drug monitoring to warn of ineffective or toxic levels and to adjust doses if needed. It is easier to measure total drug concentration after a simple blood draw, and usually the ratio of free to total drug concentration is constant. This chapter reviews different aspects of drug-protein binding.

METHODS FOR THE DETERMINATION OF DRUG PROTEIN BINDING

The most commonly used methods to determine drug binding to plasma proteins are equilibrium dialysis, ultrafiltration, and microdialysis. All have advantages and disadvantages, and results are method- and condition-specific.

As well as measuring the binding level of drugs in plasma, procedures can examine the number of binding sites, the affinity constants, and the nature of the protein involved (4) that allow interpretation of the impact of binding on drug pharmacokinetics and response. The general procedures involve separation of the free ligands,

usually small drug molecules, from bound species attached to the protein.

Equilibrium Dialysis (ED)

Introduced in 1943 (5), ED remains the most frequently used procedure (6). A membrane separates two compartments, and at equilibrium, one compartment contains the plasma or serum with protein and bound ligand, whereas free drug is sequestered to the buffer solution compartment. The unbound fraction is determined by the ratio of drug concentration on the buffer side $[D]$ divided by that in the plasma $[D] + [DP]$. Results are influenced by drug properties, proteins (content and concentration), volume of compartments, buffer strength, and ionic composition as well as by the thickness and physicochemical characteristics of the membrane (4). Time and temperature are major environmental factors, and dialysis for 4 h (or less) at 37°C has been found optimal for acidic and basic drugs (6).

In general, natural cellulose membranes are applied (7). Adsorption is low with drugs having acidic or hydrophilic characteristics. Nonspecific drug adsorption should be investigated when studying basic and lipophilic drugs (4).

In experiments, dilution or volume shifts from osmotic gradients between plasma and buffer compartments may be considerable and require correction (8). Poorly water-soluble drugs are difficult to study because use of organic solvents interferes with equilibrium distribution, and such drugs may also aggregate and adhere to membrane surfaces (7).

Ultrafiltration

Although introduced at the same time as ED (9), routine application of ultrafiltration has only recently become feasible because of improvements in membranes and equipment. Separation of the protein and bound ligand from the free drug in solution occurs using a suitable membrane that retains the proteins and is assisted either by positive pressure or more commonly by centrifugation.

The key advantage of ultrafiltration is speed (as little as 15 min), which is an important criterion for clinical monitoring situations (6) and for unstable drugs. As with ED, membrane properties and volume are important. The membranes (e.g., Amicon®) are permiselective and the cut-off can be directed at protein molecular weight sizes e.g., separation of albumin and globulins such as α 1-acid glycoprotein (AAG). However, in some cases, high-molecular-weight drugs can be retained (7). Adsorption of drugs on the membrane is problematic with low concentrations, especially of lipid-soluble ligands. Saturation of the adsorbing sites with study drug or coating with silicone has been applied to overcome such problems.

Theoretically, the free ligand concentration will be constant in the ultrafiltrate and retentate (10). Nonetheless, a decrease in concentration of free drug in the retentate will result in the dissociation of bound ligand. However, provided the ultrafiltrate is not greater than 40% of the initial volume, the free ligand concentration is not affected (11). A disadvantage of both ED and ultrafiltration for low-concentration or highly bound ($\geq 90\%$) drugs is the need for radioisotopes to provide the sensitivity for quantitation.

Microdialysis

Microdialysis perfusion is proposed as an alternative to traditional techniques for studying drug-protein interaction. Small molecules in the sample, such as a drug, diffuse in the fiber and are transported to collection vials for analysis. The dialysis membrane excludes larger molecules such as protein and drug-protein-bound drugs. The dialysate could be analyzed using standard techniques. Microdialysis perfusion is as rapid as ultrafiltration, but the samples do not suffer from re-equilibration during separation of free drug from bound drug.

Because the technique requires more chromatographic analysis, it has a longer analytical time compared with the ultrafiltration technique. This technique could be used for in vitro determination of protein binding, also, because microdialysis probes can be implanted intravenously, binding of drug could be determined in vivo under physiological conditions after dosing (12). There has been some validation of the technique used for in vitro determination of the unbound fraction of drugs in plasma. Although there is good agreement between equilibrium dialysis and microdialysis for phenytoin and racemic aminoglutethimide, the unbound fractions are significantly higher for furosemide and disopyramide using microdialysis (13). Good correspondence was demonstrated

between ultrafiltration and microdialysis for acebutolol, acetaminophen, cephalothin, chloramphenicol, isoniazid, phenytoin, salicylic acid, theophylline, and warfarin (14). It appears that the microdialysis technique may not be suitable for all compounds because of their physicochemical properties and analytical limitations (15, 16).

Pacifici and Viani (6), commenting on comparisons among results from different methods applied to protein binding, warn that methods for drug binding need to be standardized. Currently, results depend greatly on technique and interpretation of results; thus, experimental details such as anticoagulant used, type of dialysis or filtration membrane, buffer characteristics, duration of experiment, and temperature should be taken into account.

PROTEIN BINDING PARAMETERS

Drugs bind to different proteins, such as albumin, globulins (e.g., α 1-acid glycoprotein AAG and transcortin), and lipoprotein in plasma, and to tissue proteins. The reversible binding of a drug to macromolecules such as proteins is an equilibrium process. The relationship is described by the law of mass action:

where $[D]$, $[P]$, and $[DP]$ are the molar concentration of unbound (free) drug, unoccupied proteins, and the drug-protein complex, respectively, and k_1 and k_2 are rate constants for the reactions.

The equilibrium association constant for this reaction K_A is defined as k_1/k_2 and provides an index of the affinity between the binding sites and the ligand. The inverse of the association constant ($1/K_A$) is the equilibrium dissociation constant K_D for the drug-protein complex:

$$K_A = \frac{k_1}{k_2} = \frac{[DP]}{[D] \cdot [P]} \quad (2)$$

At equilibrium, the unbound fraction of drug (f_u) can be calculated from the following relationship:

$$f_u = \frac{[D]}{[D] + [DP]} \quad (3)$$

A protein can have several independent binding sites such that they may exhibit either the same or different affinities for the drug. The binding to one site may not affect binding to another site. The capacity constant (N_{TOT}) is the number of sites per mole of protein times the molar concentration of protein and has units of sites/L.

The concentration of bound drug can be expressed as the following:

$$[DP] = \sum_{i=1}^{n=i} \frac{N_{TOT,i}[D]}{K_{D,i} + [D]} \quad (4)$$

where i is the number of classes of binding sites, $N_{TOT,i}$ the capacity constant, $[D]$ the unbound drug concentration, and $K_{D,i}$ the dissociation constant for the i site. Therefore, the extent to which a drug binds depends on the affinity of the drug, the number of binding sites per molecule, and the concentrations of both drug and binding proteins.

Fig. 1 shows a plot of $[DP]$ versus $[D]$ for a single class of binding sites. As the unbound drug concentration increases, the concentration of bound sites increases. When $[D]$ is much larger than K_D , the equation predicts that $[DP]$ reaches a maximum where it is equal to the maximum number of sites N_{TOT} . The dissociation constant K_D represents the concentration of unbound drug when half the sites are occupied, $[DP] = N_{TOT}/2$. The plots of Eq. 3 after linear transformations such as the Scatchard plot, the Woolf plot, and the double reciprocal plot can be used to determine the dissociation and capacity constants. The plots will be linear when there is one class of binding sites and will be curvilinear in presence of two or more classes of binding sites on the protein or if it binds to sites in more than one protein (17). For example, the Scatchard equation for a single class of binding site is:

$$\frac{[DP]/P_T}{[D]} = N \cdot K_A - \{(K_A \cdot [DP])/P_T\} \quad (5)$$

Fig. 1 A plot of bound drug $[DP]$ versus unbound drug concentration $[D]$ for a single class of binding sites.

where P_T is the molar concentration of total protein (occupied + unoccupied), and N the number of sites per mole of protein. A plot of $([DP]/P_T)/[D]$ versus $[DP]/P_T$ gives a linear slope of $-K_A$ and a y-intercept of $N \cdot K_A$. Refined estimates of the capacity and affinity constant can be generated using a nonlinear least-squares computer program such as PCNONLIN (18).

Once the capacity and affinity constants have been obtained, the unbound plasma fraction of drug that binds to a single class of binding sites can be calculated for any value of free drug concentration:

$$f_u = \frac{[D]}{[D] + [DP]} = \frac{K_D + [D]}{N_{TOT} + [D] + K_D} \quad (6)$$

When a drug binds to two classes of binding sites such as albumin and AAG, the equation is:

$$f_u = \frac{1}{1 + \frac{N_{TOT1}}{K_{D1} + [D]} + \frac{N_{TOT2}}{K_{D2} + [D]}} \quad (7)$$

These equations indicate that the unbound fraction of the drug is dependent on the binding capacity N_{TOT} , the dissociation constant K_D , and the unbound drug concentration at equilibrium. At low free drug concentrations (i.e., $[D] \ll K_D$), the unbound fraction will be independent of change in drug concentration.

DRUG BINDING PROTEINS

Human plasma contains more than 60 proteins (19). There are three main proteins associated with the binding of drugs: albumin, AAG, and lipoproteins. This article does not review drug transport proteins of recent interest such as p-glycoproteins, organic anion transporters, and dipeptide transporters, which have been reviewed recently (20).

Albumin

zAlbumin (MW 66,300), an important binding protein present in plasma (40%) and interstitial fluid (60%) (21), which binds mostly to acidic (anionic) drugs (22) but also to cationic drugs, accounts for approximately 60% of total plasma protein (23). This water soluble protein has an isoelectric point of approximately pH 5. Therefore, at physiological pH, this protein is negatively charged, and acidic drugs bind usually to the N -terminal group. Normal serum concentrations are 38–48 g/L. Albumin is synthesized in the liver, and its half-life is approximately 19 days (23).

Two primary high-affinity drug binding sites for human albumin have been described. Binding site I, initially described for warfarin, was also shown to be involved in the binding of other drugs such as sulfonamides, phenytoin, valproic acid and phenylbutazone. Site II (the benzodiazepine binding site) binds semisynthetic penicillins and probenecid. Naproxen, indomethacin, and tolbutamide have been shown to bind to both sites.

AAG

AAG (orosomucoid) is synthesized and metabolized by the liver with a half-life of approximately 5.5 days (24) and is an α_1 -globulin protein that is smaller (MW 40,000) than albumin. It is an acute phase reactant, and concentrations increase in stress situations including diseases. At least four polymorphic patterns and four genetic variants in human plasma have been reported (25, 26).

Many basic drugs (cationic) such as propranolol, lidocaine, and neutral drugs bind significantly to AAG (normal concentration 0.07–1.1 g/L) (27) and/or to lipoproteins in addition to albumin. Generally, the affinity of a drug that binds to both albumin and AAG is higher for AAG. Because the concentration of AAG in plasma is lower than that of albumin, the AAG is referred to as a low-capacity, high-affinity protein. AAG also binds to some acidic (28, 29) and neutral drugs such as carbamazepine (17) and prednisolone (30). Interpatient variability in the plasma free fraction of several drugs such as propranolol (31), carbamazepine (32), disopyramide (33), alprenolol (34), imipramine (34), lidocaine (35), and methadone (36), is related to AAG concentration in plasma.

Lipoproteins

The lipoproteins are a heterogeneous group of proteins (MW 2,500,000 for β -lipoprotein). They are classified into four groups: chylomicrons, very low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL) (37, 38). Lipoproteins can account for 95% of total probucol binding in plasma (37). Neutral and basic lipophilic drugs most commonly bind to lipoproteins; some acid drugs may bind to a lesser extent (37). Drugs that bind to lipoproteins include probucol, cyclosporin, propranolol, lidocaine, pindolol, digoxin, digitoxin and tetracycline (37, 39–41). Quinidine and some antidepressants drugs such as amitriptyline and nortriptyline exhibit saturable binding to lipoproteins. An inverse relationship was reported between the unbound fraction of drugs and concentrations of various lipoproteins

in serum for amitriptyline, imipramine, nortriptyline, and cyclosporin (37, 39, 42).

A list of some acidic, basic, and neutral drugs highly bound (>70%) to the different plasma proteins after therapeutic doses is given in Table 1 (43).

INFLUENCE OF BINDING ON DRUG DISPOSITION

Volume of Distribution

The apparent volume of distribution at steady state (V_{ss}) is influenced by plasma and tissue protein binding according to equation:

$$V_{ss} = V_P + (f_P/f_T)V_T \quad (8)$$

where f_P and f_T are the unbound fraction of drug in plasma and tissue, respectively, and V_P and V_T are the volumes of distribution in plasma and tissue (44). The importance of binding in the plasma versus the tissue compartment is the primary determinant of the apparent volume of distribution for a drug. The distribution equilibrium of the drug in the body varies among tissues.

Tissue binding

Tissue binding can be a major determinant of pharmacokinetic characteristics of drugs, including volume of distribution and half-life. At present, no entirely satisfactory method is available for the determination of tissue binding. Sampling is invasive, and experimental animal values are difficult to validate for human correlations (45).

Examples of changes in tissue binding are the tissue displacement of digoxin by quinidine (46) and the decrease in tissue binding of digoxin in uremia (47). As a result in both cases, the volume of distribution of digoxin is decreased.

The binding of drug to tissue is usually reversible. In some cases, however, there is covalent binding, which by definition is not reversible. This applies to drug or metabolite and could be important because it could be related to toxicity (48). A good correlation has been reported in animals between the degree of covalent binding to hepatic protein and the severity of hepatic necrosis of paracetamol, isoniazid, adriamycin, and furosemide (48).

Characteristics of drugs with a large volume of distribution include weak binding to plasma proteins, high affinity to tissue protein, and high liposolubility. Increased volume of distribution can be related to an increased unbound fraction in plasma as, for example, for propranolol in chronic stable liver disease (47). Increased

Table 1 Predominant binding proteins of drugs >70% bound to plasma proteins

(From Ref. 43.)

volume of distribution could also result from shift of albumin-bound drug from the vascular to the interstitial space, as reported for ceftriaxone during open-heart surgery (49). For an AAG-bound drug, a decrease in volume of distribution would be related to an increase in binding in plasma because of stress-related conditions, increasing available AAG. Distribution equilibrium is achieved when unbound drug concentrations are the same in plasma and tissue.

Clearance

Hepatic clearance

The simple venous equilibrium model of organ clearance developed by Rowland (50) and Wilkinson (51) can be used to predict the effect of protein binding on hepatic plasma clearance:

$$Cl_H = \frac{Q(Cl_{I,u}f_u)}{Q + (Cl_{I,u}f_u)} \quad (9)$$

where $Cl_{I,u}$ is the intrinsic unbound hepatic clearance, Q the hepatic plasma flow, and Cl_H the hepatic clearance.

Other models of hepatic clearance include the sinusoidal model and the dispersion model (52). All these models assume that only unbound drug can move freely through cell membranes and that the unbound fraction of a drug measured in the systemic circulation is the same as the fraction available for hepatic metabolism. The $Cl_{I,u}$ value is measured by dividing the intrinsic clearance of total drug by the measured unbound fraction.

There is, however, evidence of nonrestrictive clearance by the liver when the fraction of drug available for metabolism may not be restricted to the unbound fraction of drug (53). Drugs that bind to AAG or lipoproteins could be taken up directly by the hepatocytes by endocytosis (54, 55).

Restrictive drug clearance

A drug is said to be restrictively cleared if the extraction efficiency by an eliminating organ (E) is less than or

equal to the unbound fraction of drug measured in the venous circulation. For these drugs, only the unbound fraction is available for distribution in the tissues, biotransformation, and excretion. For restrictive drugs with low extraction efficiency ($Cl_{l,u} \cdot f_u < Q$), a change in unbound fraction will affect the blood clearance as Eq. 9 simplifies to Eq. 10:

$$Cl_H = Cl_{l,u} \cdot f_u \quad (10)$$

The average steady-state drug concentration in plasma for a restrictively cleared and poorly extracted drug is determined by:

$$C_u = \frac{FD/\tau}{Cl_{l,u}} \quad (11)$$

where τ is the dosage interval. Therefore, a change in the unbound fraction will not affect the unbound concentration. It will then not be necessary to alter drug dosage after a change in binding in this situation.

It is important to note that an increase in the f_p value (fraction unbound in the plasma) caused by a displacement from drug during drug-drug interaction will cause only a transient rise in the unbound drug concentration, followed by a return to the predisplacement value when steady state has been reached (56, 57).

The influence of altered plasma or tissue binding on the elimination half-life depends on the relative influence of binding on the volume of distribution and the clearance. For a restrictively cleared and poorly extracted drug with moderate to large volume of distribution (i.e., >0.4 L/kg), the equation to reflect the half-life could be represented as:

$$t_{1/2} = 0.693 (V_T / Cl_{l,u} \cdot f_T) \quad (12)$$

and a change in plasma binding would have little influence on the half-lives of restrictively cleared drugs (e.g., diazepam, phenytoin) (56). For a drug with a small volume of distribution (<0.4 L/kg) such as warfarin, the $t_{1/2}$ value will be affected by a change in plasma or tissue binding.

Examples of significant drug interactions in which protein binding displacement is the major factor are phenytoin displacement by salicylic acid and tolbutamide and warfarin displacement by trichloroacetic acid, a metabolite of chloral hydrate (57). A change in dosage regimen is not necessary for phenytoin because, as described above, a displacement of restrictively cleared drugs from protein will decrease the total drug concentration but at steady state will not affect the average unbound concentrations. For warfarin, it might be necessary to temporarily adjust the dosage regimen because

this is a narrow therapeutic index drug with a long half-life and small volume for distribution.

Renal clearance

In the kidney, only the unbound drug is filtered. If the drug is not bound and there is absence of drug secretion and reabsorption, the renal clearance is a measure of the glomerular filtration rate (GFR). If the drug is protein-bound, the renal clearance of total drug in the plasma is less than the GFR, but the clearance of the free drug is equal to the GFR, as described by the relationship $Cl_R = f_u \cdot GFR$. For a drug that is either reabsorbed or secreted, the effect of altered protein binding is less predictable. Renal clearance expressed in terms of the renal processes is as follow:

$$Cl_R = (Cl_{RF} + Cl_{RS})(1 - FR) \quad (13)$$

where Cl_{RF} is the renal filtration clearance, Cl_{RS} the renal secretion clearance, and FR the reabsorbed fraction, and

$$Cl_{RS} = RBF f_u Cl_l / (RBF + f_u Cl_l) \quad (14)$$

where RBF is the renal blood flow. The clearance of drugs that undergo extensive tubular secretion (e.g. penicillins) is independent of plasma protein binding. The lack of reported side effects for the interaction of ceftriaxone with probenecid may be explained by the wide therapeutic index of the ceftriaxone (58).

Nonrestrictively cleared drugs

For nonrestrictively cleared drugs ($E > f_B$), which are highly cleared by an organ ($Cl_l > Q$), the unbound fraction is not rate-limiting because the clearance is determined primarily by the organ blood flow, and a change in unbound fraction will not affect the blood clearance. For example, the bioavailability of an oral dose will be independent of changes in blood or plasma protein binding. Changes in the plasma binding of nonrestrictively cleared drugs, given orally or intravenously, should not affect the average total drug concentration (56). Examples of nonrestrictively cleared drugs include morphine, meperidine, lidocaine (59), verapamil (60), and tricyclic antidepressants (61).

Drugs, that are nonrestrictively cleared by renal tubular secretion include penicillin and acetazolamide (57). Although significant displacement of penicillins by aspirin and sulfonamides occurs, as shown by an increase of up to 88% in unbound fractions of penicillins and no change in total drug concentration, this interaction is not clinically important because of the wide therapeutic index of these drugs (62). It is worth noting that although the clearance is

not affected by a change in binding, a change in the f_u value may affect the drug response. The elimination half-lives of nonrestrictively cleared drugs is affected in relation to the equation:

$$t_{1/2} = \frac{0.693(V_P + (V_T \cdot f_B/f_T))}{Q} \quad (15)$$

For a drug with a large volume of distribution, such as propranolol, a smaller unbound fraction in the plasma will result in a shorter half-life, a greater fluctuation during the dosage interval, and no change in the average total drug concentration. For drugs with small volumes of distribution, such as penicillins, a change in plasma or tissue binding will have little influence on their half-lives. A change in drug binding to tissues alters the apparent volume of distribution. Therefore, an increase in tissue binding will produce an increase in volume of distribution and half-life.

Concentration Dependent Binding

The degree of binding of a drug is independent of drug concentration when the molar unbound concentration is well below the dissociation constant of the drug-protein complex. Nonlinear binding during therapeutic doses may occur when the K_D value and the therapeutic concentrations are close (see Fig. 1). For valproic acid (63), the K_D value for the high-affinity site is $5 \times 10^{-5} M$, and the therapeutic range of free concentrations is 0.7 to $2 \times 10^{-4} M$. For salicylic acid (22), the K_D value is $10^{-5} M$ and the therapeutic range of free concentrations is 3 to $7 \times 10^{-5} M$. Nonlinear binding is also reported for diflunisal, an anti-inflammatory drug (64), and for thiopental (65) and diazoxide (66) all of which bind predominantly to albumin. Important examples of concentration dependent binding are shown for disopyramide (2, 67) over the therapeutic concentration range and for lidocaine at the upper boundary of the therapeutic range (68, 69). The concentration-dependent binding of prednisolone, observed at very low unbound concentrations, is explained by its high-affinity binding to transcortin (70).

For a restrictively cleared drug with concentration-dependent binding, such as disopyramide, the unbound drug concentration increases proportionally with the increase in dosage regimen. Also, with the increase in the fraction unbound, the clearance also increases. Although the total concentration also increases, it is less than proportional to the increase in dosage rate. In this case, the total concentration can be misleading, and dose adjustment should be based on the unbound concentration

of disopyramide or, if unavailable, on the patient's response (2, 71).

Blood Versus Plasma Clearance

Pharmacokinetic parameters should preferably be determined from blood, but usually drug concentration is measured in plasma or serum. Although the free fraction will be different in tissue versus plasma, the unbound concentration will be the same at equilibrium as $(f_P C_P) = (f_B \cdot C_P)$.

The determination of the blood/plasma ratio will help estimate the importance of the distribution of the drug in the erythrocytes. Drug binding to erythrocytes is usually rapidly reversible.

Drugs that bind strongly to red blood cells may exhibit concentration-dependent uptake from plasma. This is reported for acetazolamide (72), chlorthalidone (73), and cyclosporine (74). The determination of the blood to plasma (B/P) ratios can be method specific. For example, the determination of the B/P ratio of cyclosporine A increases from 1.5 to 3.0 when estimated at body temperature ($37^\circ C$) compared with a ratio of 2.5–10.0 at room temperature ($20^\circ C$) (75). Drugs reported to bind strongly to the erythrocytes (B/P ratio > 1) are promazine, chlorpromazine, propranolol, salicylate, phenobarbital, pentazocine, and phenytoin (48).

Usually, the pharmacokinetic parameters are calculated from plasma rather than from whole blood data. The use of plasma-related parameters to measure organ extraction ratios and intrinsic clearance could, however, be misleading. When drug binding is similar in plasma and red blood cells, $C_B \approx C_P$ because $f_B \approx f_P$. However, if the binding in plasma is greater than that in red blood cells, $C_B < C_P$ and $AUC_B < AUC_P$ and use of plasma clearance will provide an underestimate of the blood clearance. Maximum errors are of the order of 40%. If the B/P ratio is > 1 , the clearance determined from plasma concentrations would significantly overestimate blood clearance and could exceed hepatic blood flow.

Usually, total plasma concentration of drug is measured in plasma. The total drug concentration in blood can be estimated by:

$$C_B = C_{RBC} \cdot HCT + C_P(1 - HCT) \quad (16)$$

where HCT is hematocrit, and C_{RBC} is the drug concentration in red blood cells. Although drug binding to plasma proteins is usually rapidly reversible, some studies reported the presence of irreversible binding to albumin (e.g., the acyl glucuronide metabolite of zomepirac (76) and tolmetin (77)).

Stereoselectivity

For acidic drugs, stereoselectivity was demonstrated for both albumin binding sites I and II (78). Stereoselective binding was reported for ibuprofen enantiomers, with the mean averaged unbound fraction of the R(−) enantiomer being 0.419%, significantly less than that of the S(+) enantiomer of 0.643%. The percentage unbound of each enantiomer was concentration-dependent over the therapeutic range and was influenced by the presence of its optical antipode (79). Stereoselective binding in humans was reported for acidic drugs such as etodolac, flurbiprofen, ibuprofen, moxalactam, pentobarbital, phenprocoumon, and warfarin and for basic drugs such as chloroquine, disopyramide, methadone, propranolol, mexiletine, and verapamil. A list of human plasma protein binding of drug enantiomers was summarized by Jamali et al. (80).

Stereoselectivity in protein binding of enantiomers can also differ among species. For propranolol, a basic drug bound to AAG, the R-enantiomer binds less than the S-isomer in humans and dogs, and the reverse is observed in rat. Also, although the difference in binding is small in humans and dog, it is significant in rat (81).

Although the enantiomers of disopyramide displaced each other from AAG binding sites, resulting in a 2- to 2.6-fold change in f_u value in vitro (82), no significant enantiomer–enantiomer interaction in serum was found in vivo, presumably because of the buffering effect of serum albumin (60). The free fraction of verapamil enantiomers, determined from ex vivo volunteer samples after intravenous therapy (R-verapamil 0.06 ± 0.01 , and S-verapamil 0.12 ± 0.02), was similar to that observed in vitro in the subjects' predose serum. The free fraction of both enantiomers was higher after oral drug therapy, the R- and S-isomers being 0.13 ± 0.02 and 0.23 ± 0.03 , respectively. The difference in binding might be attributable to competition for serum binding sites from verapamil metabolites, which reach higher concentrations after oral administration (60).

A difference in the binding of the two isomers, quinine and quinidine, was reported (1, 2), and the f_u value of quinine and quinidine was $7.5 \pm 2.2\%$ and $12.3 \pm 2.3\%$, respectively, in normal human plasma.

INFLUENCE AND CONSEQUENCES OF BINDING ON DRUG PHARMACODYNAMIC EFFECTS

The free fraction of drug is most likely to relate to pharmacological effect. None-the-less, because it is

methodologically easier to determine total drug concentrations in blood or serum and the free/total drug concentration is usually constant, total concentrations are commonly applied in therapeutic drug monitoring. However, for some drugs the free/total ratio is variable, and disease conditions and drug interactions may alter it. In general, for monitoring of drug concentrations, the plasma or serum is used as the liquid of reference for practical reasons, but blood concentration is preferable because it reflects total drug concentration available for distribution.

Monitoring of Free Drug Concentrations

The monitoring of free drug concentrations may be necessary for drugs with concentration-dependent binding over the therapeutic range or in patients with diseases or conditions for which the unbound fraction of a drug could be significantly altered from normal (83). Compared with drugs that are mostly free in plasma, drugs that are highly bound ($f_u < 30\%$) would be candidates for monitoring because they are most likely to show significant differences in the unbound fraction under certain conditions.

Drugs for which total drug concentrations are usually measured and for which there would be advantage in monitoring free drug concentrations include carbamazepine, phenytoin, valproic acid, disopyramide, lidocaine, and quinidine (84–86). For disopyramide, monitoring of free drug concentration should be applied to the active enantiomer (87). However, monitoring of free concentration of these drugs in all patients is not recommended unless one of the following criteria is exhibited: 1) patients with disease likely to be associated with altered unbound fraction, 2) patients under treatment with a drug combination with potential protein binding interaction, and 3) patients showing unexpected drug response at a determined total drug concentration.

FACTORS AFFECTING PROTEIN BINDING AND CLINICAL CONSEQUENCES

Changes in protein binding may be related to factors affecting the concentration of proteins, to the variation in conformation of the binding protein such as for albumin, and to displacement from a protein binding site. The consequences of alteration in protein binding may be more important clinically for drugs highly bound ($<90\%$) to plasma proteins at therapeutic concentrations and drugs with small a volume of distribution and narrow therapeutic index (88). A list of pathologic/physiologic conditions

Table 2 Pathological/physiological conditions associated with altered protein concentrations

	Albumin		AAG	Lipoproteins
↓ Plasma protein concentration	Acute febrile infections	Malnutrition	Advanced age	Familial deficiencies ^a
	Acute viral hepatitis	Neonates/young infants	Cirrhosis	Hyperthyroidism
	Acute pancreatitis	Nephrotic syndrome ^a	Neonates/young infants	Low cholesterol diet
	Advanced age ^a	Pregnancy ^a	Oral contraceptives	
	Analbuminemia ^a	Prolonged bedrest	Pregnancy	
	Burn injury ^a	Protein-losing nephropathy	Severe liver disease	
	Cancer ^a	Renal failure

				Phenytoin or cyclosporine administration.
				Pregnancy
				Renal failure

^aConditions likely to be associated with major changes.
(From Ref. 43.)

associated with altered protein concentrations is given in Table 2.

Physiologic Conditions

Age

The plasma protein binding of drugs bound to albumin and AAG in neonates is significantly lower than that in healthy adults. AAG is low at birth and increases gradually over 12 months to reach a normal concentration (89). Factors associated with the decrease in binding are lower albumin and AAG concentrations and the presence of fetal albumin. Also, high serum concentrations of bilirubin and free fatty acids occur in the neonate, and these can compete for the albumin binding sites (90–93).

In the elderly, a small decrease in albumin concentration is associated with a small decrease in binding for salicylate (94), diazepam (95, 96), phenylbutazone (94) and valproic acid (97). Also in the elderly, an increase in concentration of AAG is associated with an increase in binding of AAG-bound drugs (98). Such an increase in AAG concentrations could be related to the greater incidence of inflammatory diseases in this population.

Pregnancy

Significant decreases in protein binding of albumin-bound drugs are reported particularly during the third trimester of pregnancy, and are related to decreased albumin concentrations and higher, concentration of fatty acids, especially during labor. As a result, increases in the unbound fraction of salicylate (70–80%) (64–69), sulfisoxazoles (70–80%) (99), phenytoin (30%) (99–101), diazepam (40–60%) (99, 100), and valproic acid (50%) (100) occur.

For AAG-bound drugs, a 35–80% increase of the unbound fraction in the third trimester is reported for propranolol (92), lidocaine (92), and bupivacaine (102). After pregnancy, whereas albumin takes 1 month to return to normal levels, AAG and free fatty acid levels return to normal within as few days of delivery (101).

Ethnicity

Formely, much of the information obtained on drugs was acquired in Caucasian subjects. A report on inter-ethnic differences in drug response showed differences in drug protein binding between Chinese and Caucasian subjects. No difference was shown for warfarin, which is an albumin-bound drug, whereas the binding of lidocaine was significantly lower in Chinese subjects and related to lower concentrations of the binding protein AAG (103). Because lidocaine toxicity is related to free drug, this difference could have therapeutic significance. A similar reduction in

the binding of propranolol and disopyramide was also reported previously (104, 105). This ethnic difference does not seem to extend to drugs bound to albumin. Studies, that examined diazepam and salicylic acid, describe findings similar to those observed for warfarin (106).

Gender, smoking, obesity, nutritional status, surgery

The unbound concentration of diazepam is 14% greater in females than in males, whereas there are no significant differences in the binding of lidocaine (107). Although McNamara (69) reported a small increase in plasma binding of lidocaine, resulting in a decrease in free fraction from 0.31 to 0.26 in smokers, another study reported no effect of smoking on the plasma binding of lidocaine and diazepam (96).

In obese women, the AAG concentrations are doubled, and the unbound plasma fraction of propranolol is 30% lower than that in women with normal body weight (108). In the obese, the albumin concentrations, and phenytoin binding are normal, whereas diazepam binding is slightly reduced (108). In undernourished or hospitalized patients, the AAG concentrations are 30–40% higher than those in unhospitalized patients, and the propranolol free fraction is reduced by approximately, 30% (109). A marked decrease in albumin concentration has been reported in malnutrition, and it seems associated with a reduction in protein synthesis (81).

In postoperative situations, with lower albumin and increased AAG concentrations, the unbound free fractions of propranolol (101) and quinidine (111) are 30–40% reduced and 100–150% higher for the albumin-bound phenytoin (112, 113). For drugs such as quinidine, which are restrictively cleared and bound to AAG, the concentration of which would rise after surgery, no effect on unbound drug concentration should be anticipated (111). In patients undergoing open-heart surgery, the unbound free fraction of ceftriaxone is up to four-fold higher compared with that in healthy volunteers because of low plasma albumin and high free fatty acid concentrations (49, 114).

Disease States

Renal disease

The most common cause of alterations in plasma albumin concentrations is hypoalbuminemia, which is associated with a variety of physiological and pathological conditions (see Table 2). This decrease in binding capacity results in an increase in unbound concentrations in plasma. Gugler et al. (115) reported a significant inverse correlation between albumin concentration and the

Table 3 Altered plasma protein binding of drugs associated with renal dysfunction

↓ Binding		↑ Binding	
Cephalosporins	Furosemide	Phenytoin	Chlorpromazine
Chloramphenicol	Midazolam	Prazosin	Lidocaine
Clofibrate	Morphine	Salicylic acid	
Diazepam	Naproxen	Sulfonamides	
Dicloxacillin	Penicillin G	Triamterene	
Diazoxide	Pentobarbital	Warfarin	
Diflunisal	Phenobarbital		
Digitoxin	Phenylbutazone		

(From Ref. 43.)

unbound plasma fraction of phenytoin in patients with nephrotic syndrome in chronic renal failure and uremia, a decrease in the binding of albumin-bound drugs was reported and related to the presence of endogenous inhibitors that accumulate (116, 117). A list of drugs associated with altered plasma protein binding in renal dysfunction is given in Table 3 (43).

Liver disease

In liver disease, the changes in drug binding may be related to a decrease in albumin and AAG concentrations attributable to either a decreased rate of synthesis or a loss of plasma proteins to the interstitial compartments. Changes may also be caused by an accumulation of endogenous inhibitors of drug binding such as bilirubin (59). For albumin-bound drugs such as diazepam and tolbutamide, the mean unbound fractions are 65–75% higher in chronic alcoholics (118) and correlate with albumin concentrations. For the AAG-bound erythromycin, the unbound fraction is two to four times higher in patients with cirrhosis compared with control subjects (119) and correlates with AAG concentrations. Increases in unbound fraction have been reported for prazosin, propranolol, morphine, diazepam, tolbutamide, phenylbutazone, phenytoin, quinidine, triamterene, theophylline, and lidocaine (48).

Pathologies associated with inflammatory conditions

AAG is a protein known as an acute phase reactant. As a result of inflammation, injury during physiological trauma, and stress (21, 39, 84, 88, 114), an increase in the binding capacity of AAG is commonly observed in patients. For a drug that is highly bound, an increase in AAG plasma levels will result in a significant decrease in unbound plasma fraction. Examples include propranolol (120), lidocaine (121), and disopyramide (34) after myocardial

infarction and propranolol and chlorpromazine (122) in Crohn's disease.

An increase in AAG concentrations after an acute myocardial infarction causes a decrease in the unbound plasma fraction of propranolol and lidocaine (nonrestrictively cleared drugs). With intravenous or oral propranolol, an increase in dosage regimen may be required (120). For lidocaine, it is recommended that normal infusion rates be used because total drug concentrations increase during long-term infusion, and the increase in binding indicates that the unbound fraction does not change significantly (121).

Cancer and burn injury

Cancer and burn injury are associated with increased concentrations of AAG and decreased concentrations of albumin in plasma. For AAG-bound drugs, a 20–30 % decrease in the unbound fractions of lidocaine (123), methadone (36), propranolol (31), and imipramine (124) is observed, whereas the unbound fractions of albumin-bound drugs increase for tolbutamide (30%) (123), diazepam (180%) (124), and phenytoin (150%) (125).

Diabetes mellitus

The decreased plasma binding of sulfisoxazole in patients with diabetes is related to in vivo glycosylation of albumin, whereas the decreased plasma binding of diazepam may be caused by high concentrations of free fatty acid displacers (126, 127).

Thyroid disease

A decrease in concentration of proteins and an increase in concentration of free fatty acids in plasma are observed in hyperthyroidism. For propranolol and warfarin, an increase of up to 20–30 % in the unbound plasma fractions has been reported (128).

Table 4 In vivo drug interactions caused by protein displacement

Drug	Displacer	Drug	Displacer
Bupivacaine	Lidocaine	Phenytoin	Salicylic acid
Carbamazepine	Valproic acid ^a		Tolbutamide
Ceftriaxone	Probenecid ^a		Phenylbutazone ^a
Diazepam	Valproic acid ^a		Valproic acid ^a
Methotrexate	Salicylic acid ^a	Valproic acid	Salicylic acid ^a
	Probenecid ^a	Warfarin	Diflunisal
	Sulfisoxazole ^a		Phenylbutazone ^a
Penicillin	Aspirin		
	Sulfamethoxy pyridazine		

^aDrugs also known to inhibit renal tubular secretion or hepatic metabolism of displaced drugs.
(From Ref. 43.)

Cystic fibrosis

Cystic fibrosis is associated with hypoalbuminemia (129). For theophylline, the unbound fraction in plasma is 30% higher in these patients compared with control subjects (129).

Drug Interactions

A change in the binding affinity of a drug may be related to the displacement by other drugs. Competitive displacement may result in an increase in the free fraction of drug in plasma, as the apparent dissociation constant (K_{Dapp}) for the displaced drug is then expressed by:

$$K_{Dapp} = \frac{K_D(1 + [I])}{K_I} \quad (17)$$

where [I] is the unbound concentration of the inhibitor in plasma, and K_I is the dissociation constant for the binding of the inhibitor.

There appear to be more cases of drug displacement involving drugs that are highly bound to albumin compared with drugs that bind to AAG and albumin. For example, the unbound free fraction of lidocaine can be increased significantly by therapeutic concentrations of bupivacaine of 3–4 mg/L (130, 131). No significant binding interaction has been reported for disopyramide, which binds almost exclusively to AAG (2). Other examples of in vivo displacement resulting in increased unbound fraction of drugs in plasma are listed in Table 4 (43).

In Vitro Artifacts

The use of vacutainer tubes and heparin was shown to alter the determination of protein binding. Heparin was shown

to decrease the plasma binding of certain drugs including phenytoin, propranolol, lidocaine, diazepam, quinidine, and verapamil (132–134). This is also an in vitro artifact attributable to continued ex vivo activity of the lipoprotein lipase enzyme and accumulation of fatty acids in the blood collection tube.

High unbound fraction of basic drugs was attributed to displacement from the AAG binding sites by a plasticizer in the cap stopper (135, 136). Since then, the stoppers have been reformulated. Storage containers and other anticoagulants have also been responsible for altering binding measurements. Binding inhibitors such as plasticizers in bags could be responsible for the alteration in the binding of disopyramide (2). The unbound fraction of phenytoin and meperidine is 80% higher in citrated plasma compared with serum or heparinized plasma (137).

Drug Regulatory Concerns

A New Drug Submission should provide information on the quality, safety, and efficacy of the drug product under the conditions of proposed use. Therefore, the chemical, pharmacokinetic, biopharmaceutical, pharmacological, toxicological, and clinical aspects should be investigated and reported. This includes detailed information on the protein binding, with an emphasis on populations at risk, such as with renal or hepatic insufficiency or when AAG may be altered. The ICH Common Technical Document on efficacy indicates the sections where proteins binding of a new active substance should be documented. The submission should include the preclinical and human pharmacokinetic information necessary to fully understand the biodisposition of the drug and its relation to the pharmacodynamic response and therapeutic and/or toxic effect. In addition, for drug–drug or other interactions, the

clinical importance of alterations in protein binding and the mechanism of the interaction should be determined, for example, if total or free concentration is affected only under initial displacement and whether these persist during chronic dosage.

It is also essential to include clinically significant protein binding information in the product monograph. In the clinical setting, the information should help explain the inter and inpatient variations in pharmacokinetics that would be reflected in variable pharmacodynamic effects and would certainly indicate when a dose or dosage adjustment is necessary. As noted above, changes in protein binding do not always require that adjustment in dosage regimens is needed, and there must be sufficient information for proper inferences to provide safe and effective therapy to patients.

PYROGENS AND ENDOTOXIN DETECTION

James F. Cooper

Charles River Endosafe, Charleston, South Carolina, U.S.A.

INTRODUCTION

A pyrogen is defined as a fever-producing agent. Pyrogens are substances that cause febrile reactions when sufficient amounts enter the circulatory system. Bacterial endotoxin is the most significant pyrogen because of its potency and ubiquity. The Bacterial Endotoxins Test has generally replaced the rabbit pyrogen test in the pharmaceutical applications.

Early Research Efforts Involving Intravenous Therapy and Pyrogens

Our awareness of pyrogens began with the advent of intravenous therapy by Sir Christopher Wren in 1656 (1). During the development of experimental medicine in the late 18th and early 19th century, many documented reports describe intravenous infusion therapy to humans that were frequently accompanied by febrile episodes. The mechanism of fever induction by infusion therapy was unknown. Since septic fever or wound fever occurred frequently when tissue from open wounds or surgical sites decomposed, physicians speculated that pyrogens might be formed in these tissues from processes such as fermentation or putrefaction. After Louis Pasteur (1822–1895) discovered that bacteria were the infectious agents that caused fermentation, there was additional thought that pyrogens were associated with bacteria. However, it was unclear whether the pyrogens were produced by bacteria or were inherently a part of bacteria. The history relevant to bacterial pyrogens in medicine has been reviewed elsewhere (2–4).

Pyrogen research beginning more than a century ago concentrated on the chemical, physiological, and pharmacological nature of bacterial pyrogens. In 1894, Centanni extracted pyrogenic substances from a large variety of bacteria, including *Escherichia coli* and typhoid (5). He also showed that these bacterial pyrogens were not proteins and that they were heat stable. Hort and Penfold's studies, published in 1912, provided the best understanding of the nature of injection fevers to that date (6–8). They used rabbits to standardize an assay for fever. By utilizing their

fever assay and the staining procedure of Gram, they demonstrated that the pyrogenic bacteria were predominately gram-negative, whereas the nonpyrogenic types were gram-positive. They were usually able to correlate the pyrogenic activity of the distilled water used in their studies with its bacterial count and showed that dead Gram-negative bacteria (GNB) were also capable of inducing pyrogenicity. They concluded that the cause of all injection fevers was a filterable, heat-stable bacterial substance.

The classic investigations of Seibert during 1923–1925 established conclusively that injection fevers were caused by heat-stable, filterable components of GNB (4, 9–11). She also successfully developed a process to consistently produce infusion fluids that could pass rabbit pyrogen assays.

Advent of Large Volume Parenteral (LVP) Solutions

Seibert's methods for producing nonpyrogenic intravenous (IV) fluids enabled hospital pharmacies to produce solutions that were safe for patient therapy (10, 11). Her manufacturing methods also launched the commercial LVP solutions industry in the decade preceding World War II. Production of today's commercial LVP solutions relies on the availability of large volumes of nonpyrogenic water, known as Water for Injection (WFI), which is typically generated by distillation. Raw material ingredients are screened for the absence of pyrogen and added to WFI. After nonpyrogenic ingredients are verified, they are mixed with the WFI in depyrogenated tanks and dispensed through filling equipment into depyrogenated containers. These filled containers are immediately autoclaved to sterilize the solution and prevent the growth of any GNB, pyrogen-producing organisms that might be present in the mixture.

NATURE OF PYROGENS

The term "pyrogen" is frequently used to describe the pyrogen most significant to the pharmaceutical industry, GNB endotoxin. Since pyrogen is a general term for any substance that causes fever after IV administration or

inhalation, it is important to differentiate nonmicrobial and microbial pyrogens. Nonmicrobial pyrogens include pharmacological agents like bleomycin, colchicine, and polynucleotide poly-I:C. For sensitized hosts, there can be antigens of human blood products, such as human serum albumin, penicillin drugs, or other therapeutic agents (12, 13).

Microbial pyrogens are by far the most significant problem for pharmaceutical manufacturers. Bacteria (killed and live), fungi, plasmodia (malarial parasites), and viruses (live) can all act as pyrogens. Additionally, bacterial products, including streptococcal exotoxins, staphylococcal enterotoxin and bacterial endotoxin lipopolysaccharide (LPS), as well as fungal products, can also act as pyrogens (13). Because the LPS component in the endotoxin is toxic in very small quantities, GNB endotoxin is the microbial pyrogen most significant for pharmaceutical producers, as mentioned above. The amount of USP Reference Standard Endotoxin needed to initiate pyrogenicity in humans and rabbits is about 1 ng/kg (14). Whole cells induce pyrogenicity when large numbers are phagocytized by the macrophages they encounter as they enter the bloodstream. Therefore, although it requires the administration of at least 10,000 organisms/kg of the most pyrogenic GNB bacteria to cause a pyrogenic reaction in rabbits (15), the number of gram-positive or fungal organisms required to induce the same effect is orders of magnitude higher, $10\text{--}10^8/\text{kg}$ (12, 16, 17).

Mechanism of Fever Induction

Endotoxin pyrogen induces fever by an indirect process. On entry into the circulatory system, endotoxin is bound to LPS-binding protein (LPB) that transports it to receptor cells in the reticuloendothelial system. The main target cells are circulating mononuclear cells, which produce proinflammatory cytokines such as interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor- α (TNF α) (18,19). These cytokines are involved in acute and chronic inflammation, induce fever, and modulate the host's response to bacterial infection (20).

Bacterial Endotoxin Pyrogen

Bacterial endotoxin is a high molecular weight complex that constitutes an integral component of the outer cell wall membrane of GNB. These bacteria constantly shed endotoxin into the environment as they grow and multiply, as well as when they die and disintegrate (21). Consequently, bacterial endotoxin can either exist in a cell-associated state or in a free state. Endotoxin that

remains cell-associated can be removed from a solution by microporous sterilizing filters, but endotoxin in a free state easily passes through most sterilizing filters. Since bacterial endotoxin is heat stable, it is not fully destroyed by a routine autoclave process. Endotoxin is ubiquitous and can be found wherever GNBs exist. Endotoxin is found in the soil, in food, in ground waters, and on any surface touched by these substances. Since the vast majority of bacteria that grow and multiply in water systems are gram-negative, bacterial endotoxin is a normal constituent of ordinary water. For this reason, it is a common contaminant in laboratories and in wet manufacturing areas, including laboratory glassware, research equipment, and water baths. It can contaminate sampling equipment, storage containers, and any reusable materials that retain moisture.

Chemical Nature and Structure of Endotoxins

Naturally occurring bacterial endotoxins contain the lipid, carbohydrate, and protein makeup of the outer cell membrane of GNB (see Fig. 1). However, most of the commercial endotoxin preparations have been purified by various extraction procedures and are generally free of nucleic acids, proteins, phospholipids, and other bacterial cell components (21). The primary chemical configuration that remains after purification is a polysaccharide structure that is covalently bound to a lipid component called Lipid A. Based on its chemical nature, which is common to various bacterial families, this substance is referred to as lipopolysaccharide (LPS). Although the terms endotoxin and LPS are often used interchangeably, most reference "endotoxin" standards are purified preparations that are more correctly described as LPS.

The Lipid A component of LPS is embedded in the outer membrane of the bacterial cell, whereas the polysaccharide protrudes into the environment (21). The polysaccharide component is composed of two parts, the core oligosaccharide that is connected to Lipid A and a longer oligosaccharide O-specific chain that is attached to the core (Fig. 2). The O-specific chain is the most variable component of the complex. It consists of 20–40 repeating units that include up to eight sugars, and it is responsible for the specific immune reaction that each type of GNB is able to evoke in a host. The core oligosaccharide is much less variable than the O-specific chain, and its influence on the host is less profound, although it can trigger antibody production in response to mutant endotoxins that lack an O-specific chain. The core

Fig. 1 Cell membrane of a gram-negative bacteria, including the lipopolysaccharide, protein, and phospholipid of the outer membrane (O-specific = oligosaccharide-specific).

is divided into the inner core that attaches to Lipid A and the outer core that links up to the O-specific chain. The inner core is the more interesting of the two segments because it bears two unusual sugars, a seven-carbon

heptose and 3-deoxy-D-manno-2-octulosonic acid KDO. KDO links the polysaccharide core to Lipid A and is found in all endotoxins, but it occurs nowhere else in nature, except in certain plants and algae (22).

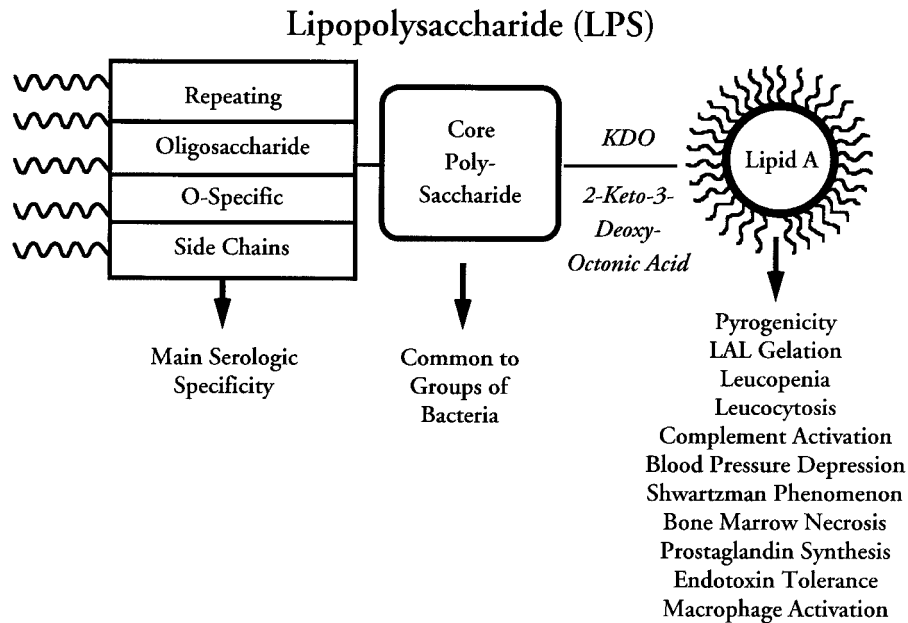

Fig. 2 The major components of lipopolysaccharide (LPS).

Lipid A is the least variable component of LPS. It consists of a disaccharide of glucosamine, which is highly substituted with amide-linked and ester-linked long-chain fatty acids, each with a backbone of about 14 carbon atoms (21). Lipid A is responsible for the vast majority of both the harmful and the beneficial biological activities that have been attributed to endotoxin. A partial list of these activities is shown in Fig. 2.

Biological Properties of Endotoxins

Bacterial endotoxins have fascinated investigators for years, in part because of their extensive and diverse biological properties and activities. Endotoxins are potent substances, which elicit a broad spectrum of the harmful physiologic responses that are produced in hosts by pathogenic GNB (21). At the extreme, they can produce profound alterations in organ function, such as hypotension and disseminated intravascular coagulation, which can lead to severe morbidity or death. On the other hand, endotoxins are also active stimulators of the mammalian defense system, which can enhance the body's capacity to cope with both microbial infections and malignant tumors. This dichotomy of biological activity continues to intrigue research scientists who are attempting to modify the Lipid A component of endotoxin in such a way that its toxic effects can be reduced or eliminated while its beneficial effects are retained (23).

Fever

Fever is one of the dramatic biological effects produced by endotoxin and one of the easiest to measure. For this

reason, it is one of the most studied and best understood of the many physiological activities that are initiated by endotoxin. The current understanding of the pathogenesis of fever is shown in Fig. 3 (21). When exogenous pyrogens enter the blood stream, they are removed from circulation by phagocytosis. The host's phagocytic cells (primarily peripheral monocytes) are thereby stimulated to synthesize a family of cytokines, or endogenous pyrogens, that are released into the circulation. These endogenous pyrogens travel to the hypothalamus, the thermoregulatory center of the body, via arterial blood supply. There the endogenous pyrogens induce various cells to increase the level of arachidonic acid metabolites (primarily the cyclooxygenase-derived prostaglandins, prostacyclins, and thromboxanes). There is considerable evidence that prostaglandin E₂ (PGE₂) is the major arachidonic acid metabolite associated with increasing the hypothalamic thermostat to febrile levels. During fever, levels of PGE₂ are elevated in the cerebral spinal fluid; the ability of aspirin and other antipyretics to reduce fever is directly

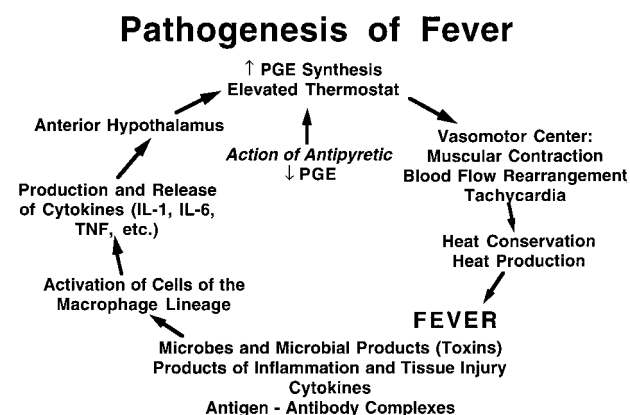

Fig. 3 The sequential events that produce fever in humans and animals.

Fig. 4 Horseshoe crabs are placed in a restraining rack and passively bled for a few minutes. They are promptly returned to the sea unharmed. Amebocyte blood cells are concentrated, washed, and lysed to produce LAL reagent. (Photo provided by J. Cooper, Endosafe, Charleston, SC.)

related to their ability to block brain cyclooxygenase. The new thermostatic setting signals the nerves that stimulate peripheral blood vessels to constrict those vessels and conserve body heat. This causes the body to chill, and the discomfort that results stimulates other physiologic mechanisms within the body to generate more heat in order to return the body to a homeostatic condition. The end result is fever (18, 24).

The systemic response to threshold pyrogenic doses of endotoxin in humans is described in studies that were conducted by the National Institutes of Health. The USP Reference Standard Endotoxin (RSE), *Escherichia coli* 0113:H10:K0, was injected into healthy volunteers at dosages ranging from 2 to 4 ng/kg (25). About 1 h after administration, a monophasic rise in temperature was observed, accompanied by chills and rigors. The chills lasted for 15 to 30 min and were followed by varying degrees of myalgias, arthralgias, headache, and nausea over the next 2 h. During this period, the subjects appeared sallow and exhibited general malaise. The peak core temperature (38.5–40°C) occurred at 3 h, followed by defervescence and symptomatic improvement over the next 3–5 h.

Septic shock

As mentioned earlier, bacterial endotoxin is a concern to the pharmaceutical industry because of its ability to induce pyrogenic reactions at intravenous dosages as low as 1 ng/kg. In higher dosages, endotoxin can be lethal. In one report, a self-administered intravenous dose of 1 mg of *Salmonella minnesota* endotoxin initiated the full clinical manifestations of septic-shock syndrome in a middle-aged laboratory worker (26). Septic-shock syndrome includes a high-cardiac-output form of hypotension, disseminated intravascular coagulation, abnormalities of hepatic and renal function, and noncardiogenic pulmonary edema. This patient was diagnosed and treated promptly and survived the episode.

Beneficial biological effects of endotoxins

Tumor reduction was attributed to endotoxin (27). Other beneficial effects of endotoxins on the host defense system include enhanced immune protection, protection from lethal irradiation, enhanced nonspecific resistance to infection, and resistance to toxic doses of endotoxin (tolerance). A hypothesis has been proposed (28) to explain the seemingly contradictory findings of the toxic vs. beneficial effects of endotoxins. It suggests that they are the primary signals that animals use to detect potentially harmful GNB and that the host defense system employs many of the body's defenses to both detect and to react against the threat of bacterial infection. This hypothesis also proposes

that the body possesses feedback mechanisms that, in most cases, attempt to match the bacterial endotoxin threat with an appropriate response. Thus, the intensity of the responses to endotoxins has evolved to maximize protection while minimizing the biological cost and self-damaging effects to the host. In general, the benefits of these responses far outweigh the risks, and when harmful events do occur, they are examples of inappropriate activity of overly protective systems (28).

Physical Properties of Endotoxins

It is important to be aware of the various physical properties of endotoxins in order to understand why they change their behavior when placed into different environments. An understanding of these physical properties is also essential for designing effective processes for depyrogenation.

Heat stability

It has long been known that endotoxins are thermostable in the presence of moist heat and that they are not appreciably destroyed by routine autoclaving processes. Early research showed that boiling was not completely effective (9). However, endotoxins can be destroyed by dry heat at temperatures above 180°C. In fact, dry heat is the method of choice for depyrogenating heat-resistant materials, such as glass and equipment.

Size

The size of endotoxin is dependent on its aggregation state, which, in turn, is dependent on its surrounding environment. In an aqueous environment, LPS is arranged in a bilayer. Its hydrophilic Lipid A components are clustered in the center of the bilayer, whereas its hydrophilic components are exposed to the surrounding solution. Bacterial LPS is stabilized by divalent cations, and in the presence of magnesium and calcium, it forms bilayer sheets and vesicles with a diameter of about 100 nm (21). However, if the divalent cations are removed from the environment, the bilayer breaks down into micellar forms that are 20–70 nm long and about 3–7 nm thick. In the presence of detergents, these micelles can be even further broken down into subunits of 0.8–1.2 nm in diameter and 10–60 nm in length.

The tendency for endotoxin to aggregate into larger and larger entities in an aqueous environment is due to the attraction that the hydrophobic groups of the LPS molecules have for one another. Aggregated endotoxin vesicles of 0.1 μm in diameter have been visualized by using electron microscopes. Even in its largest aggregation state, endotoxin passes through 0.22 μm sterilizing

filters. Conventional reverse-osmosis membranes that are nominally rated at pore sizes on the order of 1.0 nm are able to remove endotoxin from water (29). This process also removes any salts that may be present.

Molecular weight

In a typical aqueous environment that contains small amounts of divalent cations, endotoxin has a molecular weight of about 10^6 Da (21). If divalent cations are removed from the aqueous environment by chelators, the endotoxin bilayers break down into micelles of 300,000 to 1,000,000 molecular weight. When these micelles are further broken down in the presence of surface-active agents, their molecular weight drops again to about 10,000–20,000. However, these steps are completely reversible; if the detergents are dialyzed out, and divalent cations are added back to the endotoxin, the micelles and then the membranous structures reassemble themselves (30).

As the salt concentrations in water increase, endotoxin forms larger and larger molecular weight aggregates. The aggregation state of endotoxin affects both its solubility and biological reactivity. As the molecular weight of endotoxin increases, its solubility in water decreases. Additionally, as the molecular weight of endotoxin increases, toxicity in rats, rate of clearance from blood, interaction with complement, and affinity for cells also increase. However, endotoxin lethality in mice decreases as its molecular weight increases, as does its pyrogenicity in rabbits (31).

Electrostatic properties

At pH levels above 2, endotoxin aggregates are negatively charged and behave as anions (21). This property accounts for the attraction that endotoxin aggregates have for divalent cations in solutions. It is also the characteristic that provides the mechanism of action for endotoxin removal by cationically charged adsorbents.

PYROGEN TESTING

The development of the large volume parenteral (LVP) drug industry prompted the need for pyrogen testing to assure their safety. Pyrogen contamination is a greater problem for manufacturers of LVPs than it is for producers of small volume injectables because the initiation of patient fevers by parenteral solutions is dose dependent rather than concentration dependent. In other words, the onset and extent of injection fever depends on the total amount of pyrogen delivered to a patient and not on the concentration of pyrogen per milliliter of drug. Therefore,

an LVP must meet a more stringent standard for nonpyrogenicity than lesser volume drugs.

The heavy demand for LVP drug therapy prior to and during World War II and the need to ensure that commercial infusion fluids were free from pyrogens caused the United States Pharmacopeia (USP) to undertake the development of a compendial test for pyrogens (32). In 1941, the Committee of Revision of the USP authorized Subcommittee 3 on Biological Assays to begin the first USP collaborative study of pyrogen. Using *Pseudomonas aeruginosa* filtrates, prepared by the Division of Bacteriology of the FDA, the collaborative study was undertaken by the FDA, the NIH, and 14 pharmaceutical manufacturers (33,34). The study utilized the rabbit pyrogen test used earlier by Hort and Penfold and Seibert and her co-workers (7–9). Large numbers of rabbits were challenged with both pyrogenic material and physiologic saline solution. The results of the study, which were published in 1943, led to the inclusion of the first compendial pyrogen test in the 12th edition of the USP in 1942. Although refinements have been added from time to time, the USP rabbit pyrogen test remains relatively unchanged from the original format.

Basically, the pyrogen test involves measuring the rectal temperature of rabbits, both prior to and after the intravenous injection of a test solution in the ear veins. If the animals exhibit febrile responses that exceed established limits, the test solution is judged to be pyrogenic. Rabbits became the animal of choice because they are relatively inexpensive, are easy to handle, and have a labile thermoregulatory mechanism. Rabbits frequently produce false-positive pyrogen tests. For this reason, a negative result is more significant than a positive test, which makes the rabbit a good choice for assuring the absence of pyrogen in a test solution (32).

In 1969, Greisman and Hornick compared three purified endotoxin preparations on a dose-per-weight basis in rabbits and healthy adult males (35). Their results showed that rabbits and humans require approximately the same amount of endotoxin on a weight basis to induce threshold pyrogenic responses.

USP Rabbit Pyrogen Test

The USP <151> Pyrogen Test (36) is designed for solutions that can be tolerated by the rabbit in doses that do not exceed 10 ml/kg body weight and can be delivered within a time frame that does not exceed 10 min. Exceptions to these requirements are given in individual USP product monographs or federal regulations for biologics. Specifications for pyrogen test material handling,

calibration limits for recording equipment, and requirements for housing and conditioning the rabbits are also given in the <151> test chapter.

For the initial pyrogen tests, groups of three healthy, mature rabbits are chosen. Accurate temperature-sensing devices, such as clinical thermometers or thermistor probes, are inserted into the rectum of the rabbits to record their body temperature. If these probes remain inserted throughout the test period, the rabbits must be restrained with light-fitting neck stocks that permit them to move about. During the test, food but not water is withheld from the animals.

A control temperature is determined not more than 30 min prior to injection of the test dose. This is the base for determining any temperature increase resulting from the injection. Test solutions are warmed to $37 \pm 2^\circ\text{C}$ prior to injection. After injection, rabbit temperatures are recorded at 30-min intervals between 1 and 3 h. Temperature decreases are considered as zero rise. If no rabbit shows an individual temperature rise of 0.5°C or more above its control temperature, the product meets the requirements for the absence of pyrogens. If any rabbit shows an individual temperature rise of 0.5°C or more, the test is continued with an additional five rabbits. If not more than three of the eight rabbits show individual temperature rises of 0.5°C or more, and if the sum of the eight individual maximum increases does not exceed 3.3°C , the material under examination meets the USP <151> requirements for the absence of pyrogens (36).

Human Cell-Based Pyrogen Test

Pyrogens induce human monocytes to release proinflammatory cytokines such as IL-1, IL-6, IL-8, and TNF- α , as previously discussed. Test methods have been designed that include incubation of a test sample with monocytes in whole blood or in cultured cell lines and analysis of a specific cytokine after a suitable time. This cell-based methodology may provide an alternative to rabbit pyrogen testing that is required for human blood products. More development is needed to determine the optimum cytokine for analysis and to assess the nature of interference conditions (37, 38).

BACTERIAL ENDOTOXINS TEST (BET)

A *Limulus* amebocyte lysate (LAL) reagent is the basis for an in vitro pyrogen test method that is specific for bacterial endotoxin pyrogen. For this reason, it is now referred to as the bacterial endotoxins test (BET), although BET and

LAL testing are used interchangeably. When it was first introduced, there was concern by the industry and regulators that its specificity would limit its application in the parenteral industry (39). However, experience gained in this industry over the past 25 years confirms that endotoxin is the principal pyrogen of concern to pharmaceutical and medical device manufacturers. The BET has steadily gained acceptance globally as a replacement for the rabbit pyrogen test.

Discovery of *Limulus* Amebocyte Lysate (LAL) Reagent

The LAL test reagent is prepared by lysing amebocyte blood cells obtained from the American horseshoe crab, *Limulus polyphemus*. The origin of LAL reagent is traced to Frederick Bang, who first recognized the association between bacterial endotoxin and *Limulus* blood coagulation in studies of marine organisms at the Marine Biological Laboratory in Woods Hole, MA. An interest in immunity and infectious disease led Bang to study how *Limulus* would respond to an injection of bacteria. He observed that gram-negative *Vibrio* bacteria and its extracted endotoxin caused death in horseshoe crabs, not from infection but from intravascular coagulation (40).

Jack Levin, who had an interest in the effects of endotoxin on platelets and human blood coagulation, joined Bang at Woods Hole, MA, for several summers to do research on endotoxin-initiated *Limulus* blood coagulation. This collaboration produced several publications that explained a simple mechanism of enzyme-mediated interaction of LAL with endotoxin (41, 42). Levin discovered a way to harvest the intracellular fluid by osmotic lysis of stabilized amebocytes. Modern-day preparation of LAL reagent still follows Levin's basic methods.

Levin's original interest in the LAL test was for its potential as a clinical diagnostic tool for endotoxemia. However, a collaboration between Levin and Cooper produced the test's most celebrated application as a pyrogen test for the parenteral industry. The advent of short-lived radioactive drugs in the late 1960s prompted a need for a pyrogen test that was quick and required only a small volume of test material. As Cooper searched for an alternative endotoxin test for these drugs, he compared LAL sensitivity with rabbit response. The threshold pyrogenic level in rabbits was determined for LPS derived from *Escherichia coli* and *Klebsiella*. An excellent correlation was found between rabbit febrile response (fever index) and LAL reactivity (gel time), which

indicated that the *in vitro* test was indeed an indicator of a biological response (43). The LAL test yielded unmatched sensitivity and reproducibility.

Cooper and Mills set up the first commercial LAL production facility in 1971 in Chincoteague, VA, for Mallinckrodt, Inc. Production sites for LAL reagent are located on the eastern coast of the United States where horseshoe crabs are found abundantly in shallow coastal waters. The LAL test succeeded as the first “alternative to an animal test” because of amazing similarity between *Limulus* and mammalian response to endotoxin (44). The activation of human monocytes in blood by endotoxin to produce proinflammatory cytokines compares strongly to the activation of amebocytes in *Limulus* to produce clotting enzymes. As LAL reagents became commercially available, the pharmaceutical industry began to investigate the use of LAL testing as an alternative to the rabbit pyrogen test.

LAL clotting mechanism

The LAL test is based on the primitive blood-clotting defense mechanism that protects the horseshoe crab from the hostile sea of GNB that surrounds it. When a crab is wounded and invading bacteria enter its blood stream, its amebocyte blood cells respond by releasing granules that contain a coagulogen protein substance. Intracellular serine protease zymogens in the crab’s blood are triggered by the presence of endotoxin to initiate a series of activations that subsequently produce a coagulin gel clot from this coagulogen protein. The sequential activation of Factor C, Factor B, and the clotting enzyme in this coagulation cascade results in an enormous amplification in sensitivity of LAL for endotoxin.

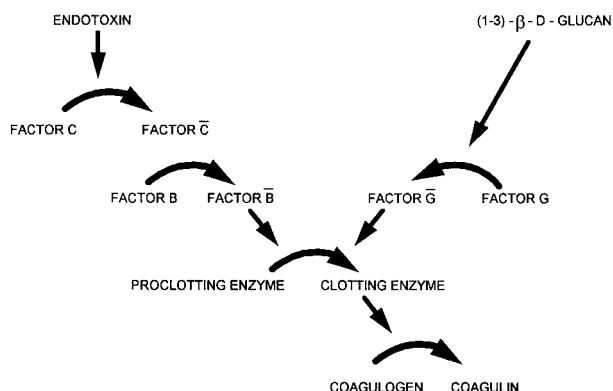

Fig. 5 Stages in the blood coagulation system of horseshoe crab amebocytes.

Figure 5 shows a coagulation scheme proposed by Nakamura (45).

The horseshoe crab is also exposed to fungus and yeast in its environment, which may explain why Factor G responds to a (1→3)-β-D-glucan, a component from the cell wall of these organisms. This pathway gives rise to a nonendotoxin activation of the LAL coagulation system (46).

Bacterial Endotoxins Test Methods

The observation of gel formation in a test tube as an endpoint for an endotoxin assay provides the means for a very simple test. The need for more objective quantitative methods has led scientists to develop a variety of automated methods for endotoxin measurement. This discussion is limited to the three methods that were accepted by the Food and Drug Administration (FDA).

Gel-clot BET

The gel-clot end point is the most commonly used endotoxin test. It is simple and requires minimal laboratory equipment and facilities. Equal volumes of test solution and LAL reagent (usually 0.1 ml each) are mixed in 10 × 75 mm glass test tubes. After incubation at 37°C for 1 h, the tubes are observed for clot formation after inverting them. Formation of a solid gel clot that withstands inversion of the tube constitutes a positive test. Each lot of gel-clot reagent licensed by the FDA must be labeled with its sensitivity (λ) to the reference standard endotoxin (RSE). The test can be used qualitatively to judge samples as positive or negative at the reagent’s sensitivity; this method is called a Limit test. The test may be also used as a semi-quantitative assay by titrating positive samples to an endpoint and multiplying the last positive sample dilution by the labeled sensitivity.

Kinetic turbidimetric assay

During the LAL-endotoxin reaction, the solution mixture becomes increasingly turbid. The kinetic turbidimetric assay (KTA) requires an incubating microplate or tube reader driven by an endotoxin-specific software. The reaction mixtures in a KTA system are continually monitored for changes in optical density in each sample that are caused by scattering and absorption of light. Generally, the KTA method measures the onset time needed to reach a predetermined absorbance by each reaction mixture. The onset times of samples are compared with those of endotoxin standards to yield quantitative values for each sample or control that contains endotoxin.

Kinetic and endpoint chromogenic assays

Unlike previously described tests, chromogenic LAL tests do not utilize the coagulogen protein from LAL reagent to produce an endpoint. Although endotoxin activates the same enzymatic cascade from the reagent, as previously described, the clotting enzyme reacts with a synthetic substrate that has been added to the reaction mixture. The substrate consists of a colorless amino acid chain attached to a chromophore. The activated clotting enzyme cleaves the bond that holds the chromophore to the amino acid; the amount released is proportional to the concentration of endotoxin (47). The chromophore that is released changes the color of the reaction mixture, thereby increasing the optical density. In the kinetic chromogenic assay (KCA), the reaction times of assay mixtures are determined with the same methods and readers used for KTA determinations. Endpoint chromogenic reactions may be done with nonincubating readers, where LAL, substrate, and quenching agent are added sequentially. After the reaction is terminated, the absorbency is read over a one-log range. In contrast, the kinetic turbidimetric and chromogenic assays may be conducted over a 2-to-4 log range.

Compendial and Regulatory Status of the BET

As confidence grew in the capability of the LAL test, as a screening tool for endotoxin pyrogen, pharmaceutical and medical device industries began to replace the rabbit test with the new *in vitro* test. The USP has continually revised the BET to keep abreast of advancements in LAL methodology.

The USP <85> Bacterial Endotoxins Test

The <85> BET first appeared in 1980 as an informational chapter in the *USP XX*. Significantly, the USP adopted the FDA *E. coli 0113* endotoxin standard as its reference standard and assigned units of potency to it (48). It also included information about calibrating a control standard endotoxin (CSE) to the RSE.

The first large-scale conversion of the rabbit test to the BET occurred in Supplement 5 to *USP XXII* when the BET became the official endotoxin test for 185 USP articles. The *USP 24* has endotoxin limits for over 650 USP articles.

Endotoxin limit

Endotoxin limits were introduced by the FDA to ensure the absence of unsafe levels of endotoxin in parenteral

products. Because endotoxin is ubiquitous, it was necessary to assign an allowable, safe limit that was below the threshold dose of endotoxin for pyrogenicity. In 1983, the USP officially replaced the <151> Pyrogen Test in USP monographs for 29 radiopharmaceuticals and five pharmaceutical waters. The USP subcommittee, responsible for revising the general chapters of the compendium, announced in 1987 its intent to replace the <151> Pyrogen Test with the BET for all USP articles for which the BET could be validated (48). Endotoxin limits were applied to USP articles using the *K/M* formula that was devised by the FDA. The endotoxin tolerance limit for humans, *K*, was set at 5 USP endotoxin units (EU) per kilogram of body weight (5 EU/kg), and *M* was defined as the maximum dose of the substance administered to an individual per kilogram per hour. The maximum dose is usually taken from the labeling of the parenteral manufacturer. The endotoxin limit for a substance is expressed in EU/mg or unit of product if it is administered on a weight basis, such as a small volume parenteral. Infusion solutions and medical device extracts have an endotoxin limit of 0.5 EU/ml. Drugs that are dosed on a volume basis also have an endotoxin limit in EU/ml.

Endotoxin limit for cerebrospinal fluid administration

Intrathecal administration applies to parenteral drugs that are infused directly into cerebral spinal fluid spaces. The tolerance limit, *K*, for these drugs is 0.2 EU/kg because intrathecal administration is the most toxic route for endotoxin pyrogen. An outbreak of aseptic meningitis followed intraspinal administration of nuclear imaging agents that were contaminated with endotoxin, but had passed the USP Pyrogen Test (49). One-milliliter volumes of the agents that had less than 10 EU per dose produced serious patient reactions and prompted the tighter endotoxin limit.

Harmonized BET

A harmonized text for <85> bacterial endotoxins test (BET) became effective in January of 2001 (50). It was a product of the International Conference on Harmonization (ICH). It was drafted by the Japanese Pharmacopeia and agreed on by the European Pharmacopeia and the USP. In adopting the harmonized BET, the USP chapter introduced radical changes. The text was simplified to make it easier to understand and follow. Whereas the previous version was a gel-clot test only, the new BET provides standardization for both gel-clot and photometric LAL methods. Any validated method may be used for a USP article however, the gel-clot method is the referee test in the unlikely case of a dispute.

FDA Validation Guideline for the LAL Test

The FDA was actively involved from the outset in developing the BET as an alternative to pyrogen testing. In 1972, a collaboration of Cooper with the FDA Bureau of Biologics (now Center for Biologics Evaluation and Research) established LAL methodology within the FDA. A study that compared LAL and rabbit tests on a group of biological and radiopharmaceutical drugs indicated that the LAL test was a rapid, sensitive, and reproducible way to detect pyrogen in these products (51). In 1973, the *Federal Register* announced the intention of the FDA to license LAL reagents as a biological product. That announcement also proclaimed the usefulness of the reagent for detecting endotoxin (52).

A *Federal Register* announcement in 1977 gave conditional approval for the BET as a release test for medical devices and biological products, provided that product manufacturers submitted appropriate test-validation data to each respective agency to amend their product's registration documents or license (53). The Bureau of Medical Devices established its own endotoxin standard and supported an industry collaborative study to develop an endotoxin limit and uniform test method for parenteral devices. As acceptance of LAL testing grew, the FDA decided to prepare a single guideline that would apply to all Agency-regulated products that were subject to screening for endotoxin. A FDA Task Force was formed with representatives from the Agency's various Centers to standardize test-validation criteria. A guideline for end-product testing by LAL methods was published in 1987 (54).

The FDA LAL test-validation guideline describes how to use all LAL methods and identifies three basic requirements:

1. The LAL reagent used in all validation, in-process, and end-product tests must be licensed by CBER.
2. The product manufacturer must perform an initial qualification of their laboratory personnel and facility.
3. Inhibition and enhancement tests must be conducted on test products to ensure that the products do not interfere with the detection of endotoxin.

This guideline has been the most influential document in LAL testing to date. Annual updates of the Appendix E, endotoxin limits for established parenteral products, were published by the FDA until 1994. With the upgrades in test procedures and endotoxin limits published in individual product monographs, the FDA no longer has a need to revise the 1987 guideline.

Overcoming Inhibition and Enhancement Conditions

Conditions for the LAL reaction with endotoxin require pH neutrality and optimum levels of sodium and divalent cations. A uniform temperature of 37°C optimizes the rate of reaction. Most therapeutic drug products require dilution with LAL reagent water (LRW) before testing to avoid interference, which is recognized by improper recovery of the positive product control (PPC). Inhibition is a failure to recover the PPC, whereas enhancement is high recovery of the PPC. Cooper (55) has described ways to identify the concentration of a substance, which is chemically compatible with the BET, and to validate the BET with drug products and excipients.

Inhibition mechanisms

There are three principal causes of inhibitory effects in gel-clot and kinetic LAL testing (55). One is an adverse chemical condition, such as a nonneutral pH, suboptimum levels of sodium ions and divalent cations (magnesium and calcium), or inhibition by trivalent cations such as soluble forms of aluminum and gadolinium. The LAL manufacturer can alleviate many of these problems by incorporating optimum concentrations of all necessary components into the LAL formula, in particular, significant amount of an organic buffer. The second important type of inhibition is loss of purified endotoxin used for the PPC. This invalidity is somewhat of an artifact because purified endotoxin, LPS, is more unstable in water than in native endotoxin, which has a stabilizing protein attached. This instability leads to container adsorption and molecular aggregation that makes the positive control unavailable for LAL detection, and this loss is not always overcome by vortex mixing. Optimum formulation of the CSE by the supplier is critical to the recovery of positive controls. Finally, interference results from inadequately controlled test parameters including test accessories, reagents, and analyst's proficiency.

Enhancement

The LAL reaction is specific for endotoxin with the exception of a glucose polymer from cellulose, yeast, and certain other microbial sources, known as (1→3)-β-D-glucan (46). This glucan activates LAL the same as endotoxin and produces a synergistic enhancement of the PPC in kinetic LAL studies. The BET allows glucan-containing products to be tested by LAL reagents that are treated to make them specific for endotoxin and avoid a false-positive result.

Preparation of a positive product control (PPC)

The PPC, required by the FDA Guideline, is a sample of the test material that contains a concentration of endotoxin that is double the labeled sensitivity of the LAL reagent (54). The PPC must be tested with each sample in a Limits test or kinetic LAL assay to ensure that a result is valid and free of interference. The most accurate and reliable technique is the “hot spike” method that requires adding 10 µl of endotoxin standard to the reaction vessel (tube or well) before addition of LAL. The gel clot method requires the addition of 10 µl of 20λ to the reaction mixture. Kinetic methods require the addition of 10 µl of a standard, 10 times greater than the spike concentration, to the wells or tubes designated as PPCs. Only inhibition is seen in gel-clot Limits tests, whereas both inhibition and enhancement are seen in kinetic LAL methods.

Sensitivity of a BET

The results of endotoxin tests for in-process solutions, bulk materials, and finished parenteral products should be reported in the same units as those assigned to the product. Two factors determine the sensitivity of a BET. For infusion solutions and device extracts, the gel-clot sensitivity or the lowest point on the standard curve (lambda for kinetic LAL) and the amount of dilution determine test sensitivity (55). For products that have an endotoxin limit in EU/mg, the choice of lambda and the concentration of the test material determine sensitivity. The formula for product-specific sensitivity (PSS) is a convenient way to calculate the sensitivity of a BET for this type of product, where:

$$\text{PSS} = \frac{\text{Lambda (EU/mL)}}{\text{Test concentration (mg/mL)}}$$

DEPYROGENATION

A process that removes or destroys endotoxin in a solution or on a material is “termed”? depyrogenation. Endotoxin is difficult to eliminate because it is ubiquitous in nature, stable, and pervious to sterilizing filters. Chemical destruction requires treatment with strong base or oxidants, which is usually too corrosive for practical use. Aseptic processing of parenteral products requires that all components, excipients, and active ingredients be made endotoxin-free (depyrogenated) before filling or assembly (55, 56). The BET is the test of choice to monitor the effectiveness of depyrogenation.

Water

Municipal water systems usually contain 5-to-50 EU/mL of endotoxin. Pharmaceutical waters are treated by ultrafiltration, distillation, or reverse osmosis to separate endotoxin from water (55). The principal source of endotoxin is bacteria within a water system in the form of biofilm or colonies entrapped in resin beds, etc. A water system will be contaminated unless there is an ongoing sanitization program. The endotoxin limit for Water for Injection was set at 0.25 EU/ml because it is a critical vehicle and a major source of pyrogens.

Glassware

Dry heat sterilization is used to depyrogenate glassware and other heat-stable materials (55, 57). Temperatures in the range of 250°–325°C rapidly inactivate endotoxin by thermal incineration. The size and mass of a load influence the time required to reach equilibrium within the oven; therefore, empirical data are required to verify that desired conditions were achieved. Overkill cycles in the range of 4–6 log reduction values (LRV) are common. A heat exposure of 250°C for at least 30 min provides greater than a 3-log reduction.

Oven cycles are most accurately challenged with an endotoxin indicator that contains 1000–10,000 EU per container in a 5- to 10-ml vial. This configuration enables complete recovery of the endotoxin challenge because it is small enough to vortex mix. Indicators are placed inside a glass pack of vials or large vessels, exposed to the oven cycle, and analyzed for log reduction.

Elastomeric Closures

Closures are traditionally sterilized and depyrogenated by a combination of washing, rinsing, and steam sterilization. All three of these steps are effective in reducing endotoxin and should be considered in the validation process. Steam sterilization as a depyrogenation process is underappreciated (58). The combined steps consistently give >3-log reduction values. The recovery of endotoxin challenge levels from closures is less efficient than recovery from glass because of the porous nature of the closure and inability to apply vortex mixing efficiently. An acceptable recovery for challenge stoppers is >10% (55).

Bulk Products

Outbreaks of pyrogenic reactions underscore the need to assign endotoxin alert limits (EAL) and to screen blood and fermentation products for endotoxin. Two clusters of

pyrogenic reactions were traced to a bulk producer of gentamicin (59). Patients reacted to endotoxin levels similar to the threshold pyrogenic dose of 4.1 EU/kg determined in a study of reference endotoxin in a population of healthy male volunteers (60).

An EAL for a bulk product is a fraction of the endotoxin limit (EL) for the finished product. An appropriate range for an EAL is at least four to five times less than the EL, depending on solubility and interference properties of the material. A validated method for a bulk substance should include a specific method to dissolve the drug and dilute it to a compatible concentration (55).

Biotherapeutic products

The elimination of endotoxin from a recombinant or fermentation product is challenging because the host organism often contributes enormous amounts of endotoxin to the bulk material. The product is usually separated from endotoxin and feedstream impurities by affinity columns.

Future of the BET

The trend among pharmaceutical and medical device manufacturers is to move from gel-clot to kinetic LAL methods to quantify results, enhance test efficiency, and improve management of BET data. Powerful endotoxin-specific software for kinetic methods addresses the needs for simplicity, comprehensive reporting, trend analysis, and compliance with software validation requirements. In the past 25 years, the BET has enabled the parenteral industry to greatly reduce the levels of endotoxin pyrogen in its products. Competition between bait fishermen and the LAL industry for the horseshoe crab has brought about coast-wide conservation measures to maintain *Limulus* resources. The BET will continue to be an essential tool for assuring the safety of parenteral products.

Quality Assurance of Pharmaceuticals

Barbara K. Immel

Immel Resources LLC, Petaluma, California, U.S.A.

Whatever you can do or dream you can, begin it. Boldness has genius, power, and magic in it.

— Goethe

INTRODUCTION

The essence of pharmaceutical quality assurance (QA) is to protect the patient and to ensure his or her safety in taking a company's drug product. One definition of a quality product is that it meets its specifications, that it is fit for its intended use, and that it satisfies the customer. Having an effective QAU is required by both United States and worldwide regulations governing the industry. Quality assurance must be independent of other departments and fully able to discharge its responsibilities and exercise its authority within a company without interference or conflict of interest. Quality assurance achieves its mission by putting necessary systems, procedures, and controls in place and continually improving them.

RESPONSIBILITIES

The major responsibilities of QA include auditing and evaluating operations, the approval of product and document quality (approval here meaning either "approve" or "reject"), and managing change control, problem investigations, and product recalls, among other tasks. Specific tasks vary depending upon whether the QA group is working with research and development on good laboratory practice (GLP) studies, in a manufacturing environment ensuring compliance with good manufacturing practice (GMP) regulations while producing clinical or commercial product, or working with medical monitors, principal investigators, institutional review boards, or contract research organizations (CROs) in complying with good clinical practice (GCP) regulations.

Quality assurance is primarily a preventive function, the goal being to put good systems, standard operating procedures (SOPs), and other needed documents in place

to consistently produce quality product, prevent problems or mistakes from occurring, and release only product, raw materials, studies, and reports that meet specifications. Products that meet specifications may still be rejected due to unsatisfactory conditions during manufacture (such as environmental monitoring excursions or other events that may affect the product's safety and purity).

Quality assurance can also be a reactive function, responding to a product quality problem or regulatory action. This group must have a written recall SOP and system (which closely follows 21 CFR 7) such that it can quickly consult with a cross-section of employees, including regulatory, research and development, clinical trial, manufacturing, quality control (QC), public or investor affairs, and legal counsel, in determining the known facts and the best course of action (and corrective action) to take, including rapidly initiating a product recall if necessary. Before discussing specific QA roles and responsibilities under the regulations, let us look at the overall process or life cycle of pharmaceutical product development.

PRODUCT DEVELOPMENT IN A NUTSHELL

In a recent PhRMA study, the average cost and length of time to develop a single pharmaceutical product from idea to marketing was estimated at \$500 million and 15 yr.^[1] A few investment-banking firms have estimated the cost to be even higher. The pharmaceutical industry has several unique features. One is that the industry exists to create products to treat disease, reduce pain and suffering, improve the quality of life, and find cures for disease. The second is that the industry is highly regulated. Obviously, to remain in business, a company must be profitable or have sustaining revenue of some sort. James Tingstad, the well-respected, now retired, columnist for *Pharmaceutical Technology*, says in his recent book, *Good Technical Management Practices*, that in our industry, the patient should always be number one because he or she is ill, followed by employees, and then by stockholders. Obviously, this involves a very difficult balancing act—balancing the needs of the patients with the needs of employees, shareholders, and investors.

Beginning with the birth of an idea, a potential new product is evaluated in research and development. Certain studies (animal toxicology or safety studies) must be performed following GLPs. If the safety data look good and the decision is made to further develop the product, an investigational new drug application (IND) is filed in order to initiate human clinical trials within 30 days of filing.

During clinical trials, all material produced to be given to patients must be manufactured according to GMPs. The stringency with which the GMPs are applied can be viewed as a continuum, with less stringent GMP requirements in clinical trials and tighter requirements in later phases. The sterility of clinical material, as well as the need to prevent any risk of contamination or cross-contamination, must be satisfactorily addressed and assured before venturing into human clinical trials.

Clinicians or others involved in conducting the trials must follow another set of regulations known as GCPs. Typically, there are three to four major phases of clinical trials for a drug or biologic product: Phase I, II, and III (Phase IV being postmarketing studies). If patient's data prove promising, and if the product has been demonstrated to be both safe and effective, a new drug application (NDA) is filed.

Before a new product gains approval to be marketed in the United States, two major steps must be taken. One is the technical or scientific review, in which reviewers from the U.S. Food and Drug Administration (FDA), and sometimes an outside advisory committee of experts, review the scientific and clinical data to determine the product's safety and efficacy. As part of that review, an FDA investigator is sent to the company's manufacturing and research facilities to perform a pre-approval inspection (PAI) or prelicensing (PLI) inspection, to see if the data are trustworthy, if applicable regulations were followed in developing and manufacturing clinical product, and if the manufacturing facility appears capable of following GMPs during commercial manufacture. The site that will be manufacturing commercial material must pass the PAI or PLI for approval to be given.

If the scientific or medical review as well as the inspection results are acceptable, the second step is approval to market. Adherence to GMPs is then required throughout the lifetime of the product. Frequently, the company will opt to begin another clinical trial to study the use of the compound for another indication, or to complete additional testing required by the FDA. Those trials must be performed following GCPs (Fig. 1).

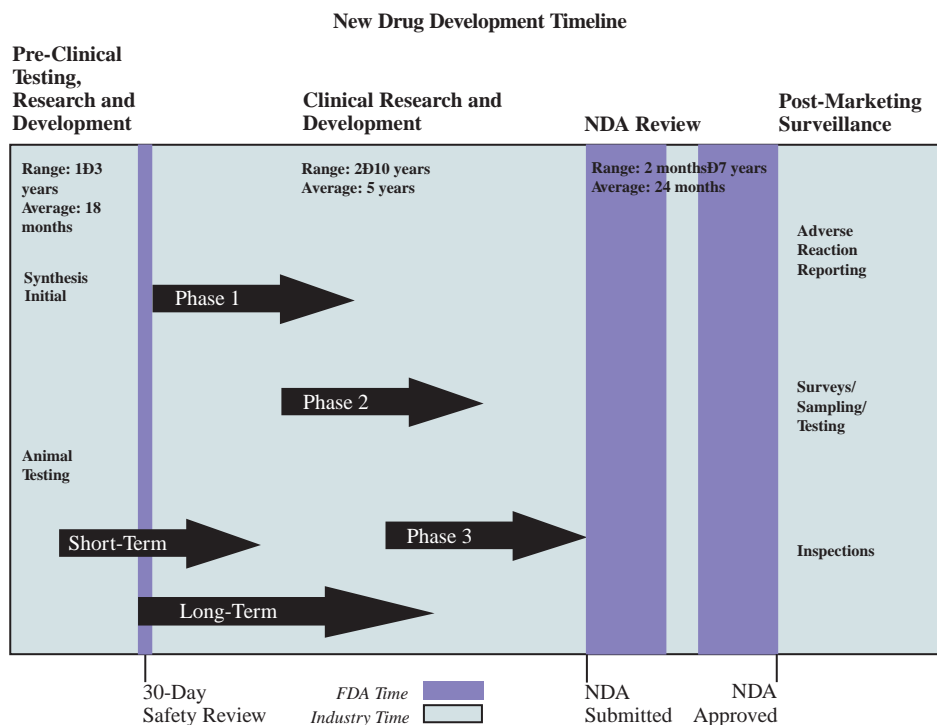

Fig. 1 New drug development timeline. (From *FDA Consumer Special Report on New Drug Development in the United States*, U.S. Food and Drug Administration, Rockville, MD, January 1995.)

GLPs

In the United States, GLP regulations (21 CFR 58) apply to safety or animal toxicology studies performed during research and development. These regulations define GLPs for conducting nonclinical laboratory studies that support or are intended to support applications for research or marketing permits for products regulated by the FDA, including food and color additives, animal food additives, human and animal drugs, medical devices for human use, biological products, and electronic products.

Compliance with this part is intended to assure the quality and integrity of the safety data filed.^[2]

Good laboratory practices require that management establish a QAU to monitor each study to assure conformance with the regulations. The GLPs also state that the QAU must be entirely separate from and independent of personnel engaged in the direction and conduct of the study.^[2]

Regulatory requirements of the QAU include:

- Maintaining a copy of the master schedule sheet of all nonclinical laboratory studies, indexed by test article and containing the test system, nature of study, date study was initiated, current status of each study, identity of sponsor, and name of study director.
- Maintaining copies of all protocols pertaining to all nonclinical laboratory studies for which the unit is responsible.
- Inspecting each nonclinical laboratory study at adequate intervals to ensure the integrity of the study.
- Maintaining written and properly signed records of each periodic inspection showing date of inspection, study inspected, phase or segment of study inspected, person performing the inspection, findings and problems, recommended actions and actions taken, and any scheduled date for reinspection.
- Immediately bringing to the attention of the study director and management any problems found that are likely to affect the study's integrity.
- Periodically submitting to management and the study director written status reports on each study, noting any problems and corrective actions taken.
- Determining that no deviations from approved protocols or SOPs were made without proper authorization and documentation.
- Reviewing the final study report to assure that the report accurately describes both the methods and SOPs and that the reported results accurately reflect the raw data.
- Preparing and signing a statement to be included with the final study report that specifies the date's inspections were made and the date's findings were reported to management and the study director.^[2]

In addition, per U.S. GLPs, the responsibilities and procedures of the QAU, all records it maintains, and the method of indexing such records must be in writing and continually maintained. Required records include internal audit (inspection) dates, the studies inspected, the phase of each study inspected, and the name of the individual performing the audit. That information as well as copies of all written procedures must be made available upon request to FDA investigators. Upon request, facility-testing management must also supply a written certification to the FDA that the internal audits have been implemented, performed, documented, and followed up.^[2]

Outside the United States, the Organization for Economic Cooperation and Development (OECD) publishes GLPs that have been adopted by its members and the European Union. These GLPs apply to the testing of chemicals to obtain information about their properties and/or their safety with respect to human health and the environment. The Japanese Ministry of Health and Welfare (MHW) has also published GLPs that apply to nonclinical laboratory safety studies that support applications to manufacture or import drugs or applications to re-examine new drugs in accordance with the country's Pharmaceutical Affairs Law.^[3]

The good news is that harmonization efforts are under way, and basic GLP principles are similar. Nevertheless, differences do exist. Major differences include the requirements for the specific contents of protocols and final reports and the retention times for records, samples, and specimens.^[3] Manufacturers must become familiar with the GLPs that concern their products, learn to which worldwide regulatory agencies their data will be submitted, and know which legislation covers the material being produced and evaluated.^[4]

Pitfalls to Avoid

Recurring, problematic areas in GLPs seem to be in documentation, training, working with and monitoring contract laboratories, and obtaining necessary management support. A noted FDA investigator and national GLP expert recently stated that the most common problems one sees may result from a general lack of support for the QAU, including:

- Assigning responsibility for the QAU to an inexperienced employee (e.g., someone who holds a business degree but lacks laboratory experience).
- Becoming complacent about training (e.g., assigning responsibility to employees who can perform the procedures but who do not know how to train).

- Misusing standardized copy to put together protocols and reports and not proofreading the documents.
- Failing to validate computerized operations.
- Management's belief that required reviews of final reports and protocols can be shortened when computers are used.
- Reduced, or nonexistent, funding support for QA.

The investigator asks which is less expensive: funding an additional one or two QA employees or not being able to use a study or include it in a regulatory submission because it was not conducted following GLPs.

Other GLP problems reported by an experienced FDA investigator include:

- GLP studies and "basic research" being done in the same laboratory without a clear division of research.
- Lack of coordination between contract facilities and sponsor of study.
- Outdated SOPs that do not reflect current practice.
- employees not following or not knowing SOPs, "maverick" SOPs.
- Inadequate review of studies, protocols, and SOPs by QA.
- Lack of documentation of installation and/or validation of equipment, computers, and software.
- Expired reagents and test articles.
- Failure to separate species (e.g., rats and pigs housed together).
- Improper archiving of records and specimens—lack of labeling or identification.
- No documented GLP training (especially for support staff).^[5]

It is critical to train and offer refresher training in not only good laboratory notebook practices but also in all job skills, test methods, and instrument systems used, and to review data rapidly. It is important that a well-respected individual provide the training. Good notebook practices are also essential to successfully file for and defend patents. A summary of laboratory notebook tips is outlined in the following section.

Twenty-Five Laboratory Notebook Tips

1. Use permanent, indelible ink when making entries. Write clearly and legibly. Remember that your audience includes not only you or your supervisor, but also the company's regulatory and QA employees, patent attorneys, and FDA and other regulatory agency investigators who may be reviewing your data years after you record it.

- Describe and provide quantities for all materials used.
2. For developmental or patentable work, state the object, purpose, and results of each experiment clearly and concisely.
3. Record all operating details and conditions, including yields, product or compound names, lot numbers of standards and reference materials, suppliers, and any expiration dates.
4. Use good scientific methods. Narrow scientific variables to one; strive for reproducibility, accuracy, and precision.
5. Develop and use approved methods. Use compendial methods whenever available. Validate non-compendial methods. Make every effort to put these suggestions in place so that you can rely upon and consistently reproduce your results.
6. Reference any methods, specifications, chromatographic data, and chart books. Include document numbers, effective dates, and revision numbers for any controlled documentation.
7. Each page must be signed and dated by the individual who makes the entry and who does the work.
8. Attach graphs, charts, etc. to notebook pages with permanent adhesive. When unfolded, attached documents should be within the confines of the opened notebook.
9. Development data should be checked, signed, and dated, or witnessed (signed and dated, with the notation, "read and understood") as soon as possible.
10. Initials are acceptable in place of a signature if the initials are on file and if this practice is written and approved in the company notebook SOPs.
11. Avoid negative or extraneous comments. Do not state opinion. Be factual.
12. For products under development, a witness must have the technical ability to witness the work but must neither have conceived the idea nor have taken part in any way in the work performed by another employee.
13. Each day's work should be started on a separate page with lines drawn diagonally across the unused portion of the previous page.
14. The supervisor or checker should sign under any diagonal lines across unused portions of a page.
15. If work is continued on a second page, start the page with the phrase "Continued from page" Each page must show the date of entry.

16. No entries should be made beneath attached sheets, and nothing should be obscured.
17. Inserts should be signed and dated by the person making the entry and checked and dated, or witnessed, by another.
18. If data are not kept in the notebook, they must be checked, signed, dated, and identified to provide a reference to the pertinent page of the laboratory notebook.
19. Lab notebooks must not be copied without the area supervisor's or QA manager's knowledge and approval.
20. Every notebook must be assigned a unique number when checked out, and reconciled when it is returned to the company archives.
21. Lab notebooks are confidential and are the property of the company. Multiple, completed notebooks should not be kept in the researcher's or analyst's work area. Filled notebooks should be returned to company archives for proper storage. Intellectual property is the lifeblood of an organization. Every company should have a system set up for the proper archival and retrieval of laboratory notebooks. A central location should be chosen, and it should be both fire- and waterproof. Proper filing should be enforced, including requiring that departing employees return their laboratory notebooks prior to their leaving the company.
22. Every company should establish a laboratory notebook policy and a record retention policy.
23. All employees must have documented training in notebook procedures and in any revisions to those procedures.
24. Take the time to organize your information with a table of contents—a table listing all experiments and the pages in which they are documented—so that the information can be easily retrieved when the company puts together a submission or prepares for an FDA inspection.
25. To reference the notebook, include the analyst's or researcher's initials, notebook number, and notebook page.^[4]

GMPs

The U.S. GMPs for drugs (21 CFR 210/211), made final in 1978, were among the first GMPs to be published by any nation. The GMPs were intended to help ensure the safety and efficacy of all products.

The regulations contain the minimum CGMP for methods to be used in, and the facilities or controls to be

used for, the manufacture, processing, packing, or holding of a drug to assure that such drug meets the requirements of the act as to safety, and has the identity, strength, quality, and purity characteristics that it purports or is represented to possess.^[10]

Responsibilities given the QA function, called the “QC unit” in GMP regulations, are as follows. The regulations state that there must be a QC unit with the following responsibilities. Besides applying to the manufacture of drugs or finished pharmaceuticals, 21 CFR Part 210 and 211 serve as a guide for the manufacture of active pharmaceutical ingredients (APIs) or biologic APIs.

- Approving or rejecting all components, drug product containers, closures, in-process materials, packaging material, labeling, and drug products.
- Reviewing production records to assure that no errors have occurred or, if errors have occurred, that they have been fully investigated.
- Approving or rejecting drug products manufactured, processed, packed, or held under contract by another company.
- Having or providing adequate laboratory facilities for the testing and approval (or rejection) of components, drug product containers, closures, packaging materials, in-process materials, and drug products.
- Approving or rejecting all procedures or specifications impacting the identity, strength, quality, and purity of the drug product.

As with the GLPs, responsibilities and procedures applicable to the QC unit must be in writing and must be followed.^[10] The proposed revision to the GMPs for finished pharmaceuticals (not yet final at the time this article was published) codify good practices already in use at many companies, including reviewing and approving validation protocols and reviewing changes in product, process, equipment, or other changes to determine if and when revalidation is warranted.^[11]

Major responsibilities include the auditing and evaluation of operations. Quality assurance must independently assess and inform senior management of the quality and compliance status of their operations, suppliers, and contractors relative to their SOPs, material specifications, company standards, and regulatory requirements. Quality assurance usually manages or supervises internal, corporate, and regulatory agency audits and accompanies auditors, unless the company has a separate compliance group to perform this function (whichever department is responsible, the responsibilities should be defined in an SOP and followed).

Quality assurance is also responsible for approving or rejecting product quality or “dispositioning” a lot. Making disposition decisions is one of the toughest jobs a QA professional will ever perform (see “Making QA Decisions”). Dispositions (whether approval or rejection) should only be made after a thorough review of all applicable records. The disposition decision should always be made by an experienced QA professional or executive, never by a junior employee or consultant, even though nothing in the U.S. regulations prohibits the latter. (In the European Union, only a “qualified person,” with the requisite experience and so designated on the company’s manufacturing or marketing authorizations, may release a lot. This requirement applies to any lots to be released or sold in the European Union.)

In discharging their review and approval responsibilities, QA must review the adequacy of procedures, methods, sample plans, test methods, and internal and external specifications and approve SOPs, specifications, methods, validation plans and results, and related documents. The QC unit must also approve raw materials, components, facilities (including both internal facilities and those of suppliers and contractors) and in-process and finished goods.

Where there is a program allowing Production or another department to perform required inspections and tests, the program and results of its activities shall be subject to QA periodic audits or monitoring. This monitoring may include QA inspections and tests performed in parallel or in place of Production.

Quality assurance must approve each batch to be marketed by the unit, manufactured by the unit for use in clinical trials, submitted to regulatory agencies in support of registrations, or used to support validation of a process.

Purely experimental batches do not require QA approval. All approval must be based on a thorough QA review of the adequacy of the facility, its procedures, methods, records, inspections, and test results, prior to batch release. This applies to both internally manufactured batches and those made by contractors.

Finally, QA is also responsible for managing change control, problem investigations, and product recalls. QA must review and approve change, control SOPs, and ensure that QA activities are completed by approving proposed changes based on the impact of the change on quality and compliance with the regulations.

Quality assurance must approve written problem investigation SOPs, evaluate investigations, approve actions, and ensure that corrective and preventive follow-up is done. QA must identify and lead to conclusion any situation that requires a recall of a distributed product or similar action. Recalls are one of the toughest situations a

QA professional will face. Items to consider in a recall meeting are given later in this article.

Common sense dictates that the head of QA may not be at a lower organizational reporting level than the head of Production. To minimize conflicts of interest, the head of QA should not have routine accountability for processing, packaging, purchasing, production planning, engineering, or inventory control. Groups that develop data used for QA decisions, such as laboratories and inspection departments, usually report to QA but may report to another non-Production area such as R&D. The QC laboratory, which routinely performs tests of raw materials, in-process materials, and finished product, is not a manufacturing support operation.^[18]

Major Tasks

Common tasks of a QA group involved in manufacturing clinical or commercial product include the following:

- Controlled documentation and record-keeping.
- Batch record (the “recipe” for manufacturing each lot) issuance and review.
- Batch or lot disposition (approve or reject).
- Internal audits.
- Review of (may help write) regulatory submissions).
- Change control.
- Problem investigations (including deviations, nonconformances, yield discrepancies, out-of-tolerance results, and so on).
- Customer complaints.
- Annual product reviews (review of all lots of each commercial product).
- Environmental monitoring and control.
- Training.
- Stability program.
- Retention of retains and samples.
- Sampling.
- Validation.
- Handling quality crisis.
- Making recall decisions.
- Escorting outside investigators, responding to regulatory agency inspection reports or communications.
- QC laboratory—performs all testing.^[18]

Making QA Decisions

When reviewing the seriousness of a product or quality problem and deciding whether to release a lot, consider the following questions.^[15] Please note that even a lot that meets its specifications may need to be rejected,

based upon environmental monitoring or other serious excursions.

- Does the product meet its specifications?
- What is its indication? What is the product used for: heart patients? immunocompromised patients? pediatric or elderly patients? (Please note that the critical item in a recall situation is whether there is a flaw in the product, not the indication for the product.)
- What is the dosage form? How is the product delivered? (Injectables are among the most demanding of dosage forms because their contents are immediately delivered to the bloodstream.)
- How serious is the problem? What is the risk involved? Is contamination a possibility? If so, what is the organism and its probable source? What does the contaminant do to people when delivered by your dosage form?
- What do the environmental monitoring data look like? Did the product pass a sterility test? (The results of environmental monitoring—including operator touch plates and EM data for the facility, air, water, and equipment—are more important than sterility tests, which do not guarantee sterility. Please note that the environmental monitoring data are also extremely important for the bulk drug substance for a biologic product.)
- Should this product be released? Would you take medication from this lot? Would you give it to your child?
- Finally, what other products or lots are affected? Were the same equipment, air, room, materials, or stoppers used for another product or lot? Look for the “ripple effect”: Other products might be similarly affected. If they to are affected or suspect, they too must be thoroughly investigated.

Items to Consider in a Recall Meeting

This information^[6] is not all-inclusive. Please consult your company’s QA executive, legal counsel, quality advisory team, recall procedure, or the specific regulatory requirements for handling a recall in the Code of Federal Regulations (21 CFR 7).

Identifying scope of the problem:

- Which product? Indication?
- How many units or lots?
- When and where distributed?
- Other products or dosage forms affected?
- When and how did you learn of the problem?
- Internal discovery or test result? If yes, give details.

- External discovery? If so, give nature and details of original complaint, with name, phone number, and address of source.
- Has corrective action been taken?
- Has there been any reply to the complaint?

Determining the cause of the problem:

- If unknown, what are probable causes?
- How is it being investigated?
- How soon will cause be identified?
- Did product fail to meet specifications?
- Is product or device being used for treatment or diagnosis?
- Relationship, if any, of the product or device to reported incident or adverse event?

Classifying the recall:

- Risk to patient?
- Life-threatening problem?
- Product indication and patient population?
- Seriousness of defect or recall issue?

Conducting the recall:

- Notify distributors—get confirmation of receipt.
- If life threatening, get all units back and destroy them, document their destruction, and ensure traceability.
- If a few units affected, notify by phone and follow-up by letter.
- Write a script for the phone work, and insist that individuals follow that script, so they do not babble.
- If sales technical representatives installed the product (such as with a device or instruments), have them retrieved.
- Before distribution, have the recall letter first reviewed by legal counsel; the letter should succinctly tell the recipients only the necessary information. Clearly identify the letter as a recall letter.
- Follow your recall SOP. Plan to conduct recall effectiveness checks.
- Notify the FDA local office (or the appropriate world regulatory agencies if your product is available outside the United States).
- Identify the product(s) and scope of the problem (all lots or units).
- What is the cause if known (if not, working on it)?
- What are the risks and the recommended classification of the recall?
- Is a 72-h field alert needed? A medical device report (MDR)? Biologic product errors and accident (E/A) report?

- How do you plan to conduct the recall? Have all affected lots (and/or products) been identified?

This last point is very important to avoid doing one recall and then having to do another a few days or weeks later. Such behavior also does not make regulatory agencies feel comfortable about either the state of control or the ability to handle a recall.

Pitfalls to Avoid

According to FDA compliance executives with the Center for Drug Evaluation and Research (the division that regulates drugs), recent GMP compliance problems include:^[16]

- Lack of process and computer validation.
- Out-of-specification results inadequately investigated.
- Failure to investigate injury complaints.
- Cross-contamination due to improper equipment cleaning, particularly with APIs.
- Lack of complete validation for aseptic processing.
- Poor practices by operators in aseptic areas.
- Inadequate environmental monitoring.
- No validation of analytical methods.
- Inadequate employee training.
- Failure to demonstrate that analytical methods used for stability testing indicated stability.

Common reasons for GMP warning letters and deficiencies observed during pre-approval inspections include laboratory controls, production and process controls, records and reports, and validation (cleaning, process, assay, and computer).^[17]

Every major world nation has its own version of the GMPs, although the basic principles are the same. European Union GMPs define pharmaceutical QA as a “wide-ranging” concept that covers all matters which individually or collectively influence the quality of a product. It is the sum total of the organized arrangements made with the object of ensuring that medicinal products are of the quality required for their intended use”.^[13] The U.S. FDA is widely viewed as one of the toughest regulatory agencies worldwide. Other world agencies such as the Medicines Control Agency (MCA) and European Medicines Evaluation Agency (EMA) based in London, BfArM (the German agency), the Health Protection Branch (HPB) of Canada, and Koseisho or the Japanese Ministry of Health are also viewed as being quite stringent. A general consensus (among Americans, in any event!) is that if you are fully in compliance with all International Conference

on Harmonization (ICH) guidances and the U.S. regulations, you will most likely be in compliance with other world regulations.

GCPs

Good clinical practices are regulations governing the conduct of human clinical trials. In the United States, regulations that govern this discipline include the following:

- 21 CFR 50: protection of human subjects.
- 21 CFR 56: institutional review boards.
- 21 CFR 312: IND.
- 21 CFR 314: NDA.
- 21 CFR 320: bioavailability and bioequivalence requirements.

Members of the European Union follow *Good Clinical Practice for Trials in Medicinal Products in the European Community* and *The Manufacture of Investigational Medicinal Products*, an annex to the *EC Guide to Good Manufacturing Practice*. The Japanese MHW has also published GCP regulations. However, since the publication of guidelines by the ICH, a consortium of individuals working to set a unified standard for the European Union, Japan, and the United States, the ICH GCP consolidated guidance has become the de facto standard for conducting clinical trials. The ICH guidance was developed taking into account current GCPs of the European Union, Japan, United States, Australia, Canada, the Nordic countries, and the World Health Organization (WHO).^[6]

The ICH guidance defines QA as “All those planned and systematic actions that are established to ensure that the trial is performed and the data are generated, documented (recorded), and reported in compliance with GCP and the applicable regulatory requirement(s).” Quality control, on the other hand, is defined as “The operational techniques and activities undertaken with the QA system to verify that the requirements for quality of the trial-related activities have been fulfilled”.^[6]

Specific responsibilities assigned to the QA/QC group of the company sponsoring the trial (the “sponsor”) are as follows:

- The sponsor is responsible for implementing and maintaining QA and QC systems with written SOPs to ensure that trials are conducted and data are generated, documented (recorded), and reported in compliance with the protocol, GCP, and the applicable regulatory requirement(s).
- The sponsor is responsible for securing agreement from all involved parties to ensure direct access to all

trial-related sites, source data/documents, and reports for the purpose of monitoring and auditing by the sponsor, and inspection by domestic and foreign regulatory authorities.

- Quality control should be applied to each stage of data handling to ensure that all data are reliable and have been processed correctly.
- Agreements made by the sponsor with the investigator/institution and/or with any other parties involved with the clinical trial must be in writing either as part of the protocol or in a separate agreement.

The guidance also requires that the sponsor ensure that all clinical trial materials are manufactured in accordance with applicable GMPs.^[6] In the clinical setting, duties that normally would be performed by QA in a manufacturing or GLP environment (such as selecting, monitoring, or auditing of the site, training, and so on) may be performed by clinical research associates (CRAs), the medical monitor's staff, or the CRO's staff. Who performs the work or what the department is called is not as important as ensuring that the required work is being thoroughly performed, documented, and monitored.

Pitfalls to Avoid

The clinical field is changing rapidly, and clinical professionals must stay abreast of the changes. There are major differences between the European, United States, Japanese, and ICH requirements, particularly in their organization and detail, although all four versions address the key issues. Any company wishing to conduct human clinical trials in any country must become familiar with and comply with all applicable regulations. At the time of the publication of this article, it was still a requirement that any company wishing to market a product in Japan, conduct clinical trials in Japan (despite the adoption of the ICH guidelines). And since the recent death of the young man participating in a gene therapy trial in the United States, clinical trials have been under increased scrutiny and enforcement. In the United States, inspections done to enforce GCP and GLP compliance are termed "bioresearch monitoring" inspections.

Problem areas reported by an experienced FDA investigator during inspections of clinical investigators include protocol violations, insufficient recordkeeping, failure to have consent forms completed prior to subject's beginning the trial, reporting of adverse events, and drug accountability (inventory recordkeeping).

Problems noted during inspections of the Institutional Review Board (also known as the Ethics Committee in Europe; the group that reviews and approves the research to be done in that facility, the clinical protocol, investigator's brochure, and so on), again by an experienced FDA investigator, include:

- Lack of written procedures.
- Lack of membership requirements.
- Not requiring an investigator's brochure.
- Inadequate informed consent.
- Approving research while lacking a quorum.
- Inadequate recordkeeping, particularly minutes.
- Inappropriate use of emergency approval.
- Inappropriate use of expedited approval.
- Inadequate continuing review of research.^[5]

Sponsors of clinical trials, their monitors, and/or the CROs they delegate to, are responsible for:

- Obtaining FDA or other world regulatory agency approval, where necessary, before study begins (some studies require the filing of an IND; simpler studies may sometimes be initiated after the approval of the Institutional Review Board or Ethics Committee).
- Manufacturing and labeling investigational products appropriately.
- Initiating, withholding, or discontinuing clinical trials as required.
- Refraining from commercialization of investigational products.
- Controlling the distribution and return of investigational products.
- Selecting qualified investigators to conduct studies.
- Disseminating appropriate information to investigators.
- Selecting qualified persons to monitor the conduct of studies.
- Evaluating and reporting adverse experiences.
- Maintaining adequate records of studies.
- Adequately monitoring clinical investigators.^[5]

Sponsors may transfer responsibility for any of their obligations to an experienced, reputable CRO, but under the regulations, such transfers are permitted only by written agreement. Responsibilities not specified in the written agreement are not transferred. Effective monitoring by the sponsor or their CRO is considered critical in preventing fraud at clinical sites. The monitoring or auditing is usually done by a QA employee, or someone performing that role for the sponsor.^[5]

INTO THE FUTURE

A recent PhRMA survey shows that from 1980 to 1997, the number of employees in QA/QC and Production decreased by 10,000—a reduction of 11.7%—while the number of medical R&D and marketing employees nearly doubled.^[2] Could there be any correlation between these statistics and the spate of GLP, GMP, and GCP warning letters and other regulatory actions taken against companies by the U.S. FDA?

There may be fewer QA/QC employees because work is being outsourced, there is more automation, and there is a reduction in force and plant consolidations as a result of mergers. Perhaps, in the push to speed products to market and cut costs, manufacturers are harming themselves by insufficiently staffing some areas, not always providing adequate training or supervision, making do with temporary employees, and operating by triage.^[4]

The consequences, however, for regulatory violations and severe quality problems in the United States depend upon the severity and duration of the issue at hand. The worst possible ramification, of course, is that a patient would be injured.

U.S. regulatory ramifications for noncompliance include invoking the application integrity policy (for fraud), serious inspection observations, a warning letter, import alerts, withheld research and/or product approvals, cancellation of government contracts, product recalls, seizure, consent decree of permanent injunction, civil money penalties, suspension or revocation of licenses, and prosecution (including indictments and temporary or permanent debarment, if found guilty).^[5]

Clearly, it is in every company's self interest to not only put the patient first, but also to follow all applicable regulations. In the recent past, we have seen extremely expensive civil money penalties, with the most expensive one to date being \$100 million for repeated GMP violations over a 6-yr period.^[13] As we enter the 21st century, let us commit to doing the right thing, putting patients first, investing in necessary resources, systems, and innovations to not only ensure patient safety but also continually improve our operations, and commit to remaining current with changes in worldwide regulatory expectations and meeting at least the minimum required regulations. Any company can have an effective QA system by:

- Putting meaningful, useful systems in place
- Continuously implementing improvements
- Having good and/or seasoned QA and QC professionals
- Having sufficient number of employees
- Giving employees a voice

- Having the support of senior management
- Conducting thorough problem investigations that determine and address root causes
- Remaining current with all applicable regulations and proposed regulations
- Networking with peers to remain current with industry practice
- Funding both compliance and business improvements
- Training and developing its people
- Staying current with what regulatory agencies, investigators, and inspectors are asking about.^[6]

Not having an effective quality system and continuing to be in noncompliance with regulatory agency requirements or expectations will most likely lead to serious consequences. We all have a responsibility to minimize risk—to the patients we serve as well as to our companies.^[6]

Regulatory Timeline

Pure Food and Drug Act. Creates one of the first government regulatory agencies (now known as the FDA); the culmination of 25 yr of lobbying, this act makes it illegal to sell “adulterated” or “misbranded” food or drugs.

Federal Food, Drug, and Cosmetic (FD&C) Act. *Tragedy:* Sulfanilamide “elixir” made with poisonous solvent causes 107 deaths. *Result:* Requires manufacturers to prove the safety of products before marketing.

Two Unrelated Events. Insulin amendment requires FDA to test and certify purity and potency of insulin. *Tragedy:* Nearly 300 deaths and injuries from distribution of sulfathiazole tablets tainted with phenobarbital. *Result:* FDA revises manufacturing and quality controls drastically, the beginning of what will later be called GMPs.

1962: Kefauver–Harris drug amendments. *Tragedy:* Thalidomide, a sleeping pill and treatment for morning sickness, causes birth defects in thousands of European babies. *Result:* Manufacturers must prove efficacy of products before marketing them and ensure stricter control over drug testing.

1978: CGMPs final rule for drugs (21 CFR 210/211). Establishes minimum CGMPs for manufacturing, processing, packing, or holding drug products.

1979: GLPs (21 CFR 58) final rule. Establishes GLPs for conducting nonclinical laboratory studies that support applications for research or marketing permits for human and animal drugs, medical devices for human use, and biological products.

1982: Tamper-resistant packaging regulations issued for OTC products. *Tragedy:* Acetaminophen-capsule poisoning by cyanide causes seven deaths. *Result:* Revision of GMPs to require tamper-resistant packaging.

1983: Two unrelated regulatory events. The Guide to the Inspection of Computerized Systems in Drug Processing initiates tighter controls on computers and computer validation. Federal Anti-Tampering Act makes it a federal crime to tamper with packaged consumer products.

1987: Guideline on general principles of process validation. FDA expectations regarding the need for process validation are outlined.

1992: Generic drug enforcement act. Precipitated by illegal acts involving abbreviated NDAs. *Result:* Created debarment penalty and initiated PAIs for all drug applications.

1996: Two unrelated events. Proposed revision to U.S. CGMPs for drugs and biologics (21 CFR 210/211) adds detail for validation, blend uniformity, prevention of cross-contamination, and handling out-of-specification results.

ICH Guidance for Industry: E6, GCP: consolidated guidance from ICH becomes the de facto standard for conducting human clinical trials.

1997: Electronic records final rule (21 CFR 11). Requires controls that ensure security and integrity of all electronic data.

1998: Draft guidances. Manufacturing, processing, or holding APIs and investigating out-of-specification (OOS) test results for pharmaceutical production.

Definitions and Other Useful Information

The following definitions are abstracted from the requirements of laws and regulations enforced by the U.S. FDA.^[9]

The FD&C Act defines drugs as “articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals” and “articles (other than food) intended to affect the structure or any function of the body of man or other animals.” It is the intended use that determines whether something is a drug. Thus, foods and cosmetics may be subject to the drug requirements of the law if therapeutic claims are made for them. The FD&C Act prohibits adulteration or misbranding of any drug and requires the “new drugs” be reviewed and approved by FDA before they go to market.

Adulteration means contaminated with filth or putrid. Over the years, the definition has been expanded to include products that are manufactured without following GMPs.

Misbranding applies to statements, designs, or pictures in labeling that are false or misleading as well as to the failure to provide required information in labeling.

Drug applications typically fall into three categories: an NDA, a new animal drug application (NADA), or an abbreviated new drug application (ANDA) for generic products.

Any individual found guilty of breaking the required regulations or performing a prohibited act per the U.S. FD&C Act (such as adulterating or misbranding a product) can be fined up to \$250,000. Any corporation or partnership found guilty of committing a prohibited act can be fined up to \$1 million.

ACKNOWLEDGMENTS

The author gratefully acknowledges Carolyn Hall of Dekker for all her unbelievable patience, hard work, and effort in seeing this chapter into print, as well as the entire Dekker editorial and production staff. Special thanks to John Parker, Ph.D., for recommending the author. The author also wishes to thank everyone who served as a source for this article, as well as Anne Montgomery of BioPharm Magazine and Stefan Schuber of Pharmaceutical Technology. Last but not least, the author gives lifelong thanks to Linda Smith of Genetics Institute, who graciously reviewed this chapter, to her clients, and to Maureen O'Connor and the former employees of Syntex Corporation (now Roche Bioscience) for teaching the author and many others about good quality assurance. Thank you all very much.

Quality Systems Management

Gary C. Harbour

Pharmacia Enterprises S.A., Luxembourg-G.D., Luxembourg

Robert G. Kieffer

RGK Consulting, Palm Desert, California, U.S.A.

INTRODUCTION

Managing for quality is and always has been a critical task of management no matter what the industry. In the pharmaceutical industry today, achieving quality of products, services, and processes is as important as it ever was; however, today we need to achieve it with reduced resources. We need to do more with less. We need to be as concerned with the quality system's efficiency as well as its effectiveness. Rising regulatory and customer requirements make this ever more challenging.

In this article, we will define the components of the quality system. We will present the pros and cons of various models of a quality system—drug GMPs, the medical device quality system regulations, ISO 9000, and the Malcolm Baldrige award criteria. In addition to guidance on the design of the quality system, we will describe some techniques that we have found to be effective in managing it.

THE QUALITY SYSTEM

Traditionally in the pharmaceutical industry, the quality function is divided into two parts, quality control and quality assurance. Quality control centers on testing products to assure their compliance to specification. It is in general concerned with evaluating events from the past. FDA has recognized this deficiency with the often-quoted philosophy that “you cannot test quality into a product.” Quality assurance is focused on building quality into a product through activities like validation, process and environmental control, and documentation. Quality assurance is in general concerned with events in the present. Only relatively recently has the pharmaceutical industry begun to emphasize a quality management accountability for continuous improvement of processes, people, and culture. Quality management is about the future, about prevention, and management's role in improving the quality system.

A system is a group of parts, components, or processes that work together to achieve a common goal. For the

quality system, the common goal is understanding and meeting customer's needs. The components of the quality system are processes, people, and culture (see Fig. 1). There are four types of processes that comprise the system:

- **Management**—the management processes are the most important. Some of the management processes that are critical to the quality system are: the communication of policy, standards, directions, objectives, and priorities to the organization; periodic reviews of the quality system's health and need for improvement; creation of the quality culture; and ensuring the availability of adequate resources.
- **Core**—the core processes are those that produce product for sale to a customer. For each step in the core process, the critical control points or variables and the acceptable ranges of these variables must be identified. The controls may be done in process by production or off-line in the QC labs. The quality of the core process depends principally on the design of the process and its validation; i.e., on its intrinsic capability.
- **Supporting**—some of the key supporting processes in a GMP plant are: audits, change control, failure investigations, labeling (artwork generation, labeling use and control), maintenance, materials management, complaint handling, product release, stability/expiration dating, training, trend analysis, and validation. Supporting processes add value in proportion to their contribution to the core process.
- **Supplier**—the supplier process is essential for the proper functioning of the core process. The quality of the core process depends to a large degree on the quality of incoming raw and packaging materials. The goal is supplier partnership. The quality of the supplier's own processes directly impacts the quality of your core process.

The focus on process quality is important because the work gets done through processes. The quality of the output depends on process quality and efficiency gains come from process improvements. It is also necessary to remember, “over the long haul, strong people cannot

Fig. 1 Quality system components.

compensate for a weak process. All too often, management relies on individual or team heroics to overcome fundamentally flawed processes.”^[1] The principal components of a process are shown in Fig. 2. The most important component is ownership; i.e., the process is actively managed. One generally finds that departments are managed but processes are not. For internal processes, the supporting processes, the inputs, and outputs are generally information; information that is supplied by internal suppliers and used by internal customers. The activities in the process should be value added. It is not unusual to find that nonvalue added activities in the pharmaceutical manufacturing plant exceed 25%.

The second component of the quality system is people. Given that we have capable processes, we then need people with the requisite knowledge and skills. We have to hire and promote people with the potential for the task and importantly with the correct attitude. We need to develop them to their full potential. If we have high performance standards, all employees will have training needs. These must be prioritized. A tool for the determination of training needs and their prioritization is described in Ref. 2. Adequate time and resources must be allocated to training. World-class companies allocate about 100 hr yr⁻¹ per person for training. If improved

performance is the goal of training, its effectiveness must be evaluated by observation of performance or by improvement in business metrics.

The third component of the quality system is culture. Given capable processes and skilled employees, management needs to create a culture that fosters the desired behavior and that supports the natural motivation of employees to take pride in a job well done. Some aspects of the quality culture are:

- There is a clear vision of the desired future and how to get there.
- Management leads by example—if quality is number one, it is number one on management’s agenda and decisions are made accordingly.
- Performance standards are high, employees are held accountable for their actions and performance feedback is frequent, with emphasis on positive feedback.
- There is a lack of fear in the workplace, innovation/improvements are encouraged with the understanding that sometimes mistakes will be made.
- Individuals are respected and participate in the management of the organization to the extent of their capabilities.
- Learning, individual and organizational, is valued.
- Teamwork is fostered.
- Adequate resources are provided.

MODELS OF A QUALITY SYSTEM

The Food and Drug Administration’s (FDA) manufacturing regulations for drug products were published as Current Good Manufacturing Practice for Finished Pharmaceuticals in the Federal Register, Vol. 43, No. 190, September 29, 1978. These cGMPs along with various guidances published since 1978 provide the rules by which drug products to be sold in the United States must be manufactured. The cGMPs are not a good model of a quality system. They are not structured as a system, but are more a set of specific rules. In this limited sense, they define compliance but miss the mark in defining an adequate quality system. There are some significant flaws, vagaries, and omissions in them. The basic philosophy of these cGMPs is the philosophy of quality of the 1950s and 1960s—control, inspect, do not trust production, and the QC/QA department is responsible for quality.^[3]

A good model of a quality system is provided by FDA’s Quality System Regulations for medical devices.^[4] It is based on the ISO 9000 standard. These regulations are based on a modern, up-to-date philosophy of quality. They view quality as a total system, hold management responsible for quality, and emphasize the importance

of design and quality planning.^[3] Furthermore, FDA's inspections of medical device plants are system based.^[5]

Our recommended model of a quality system for a plant producing drug products is ISO 9000:2000, with the addition of the rules specific to drug products taken from the cGMPs. ISO gives the requirements for a quality management system, while the cGMPs gives the compliance requirements. The year 2000 version of ISO 9000 represents the current best thinking about quality and how to achieve it.^[6] The quality management principles as listed in Table 1 represent the philosophy upon which the quality system is built.

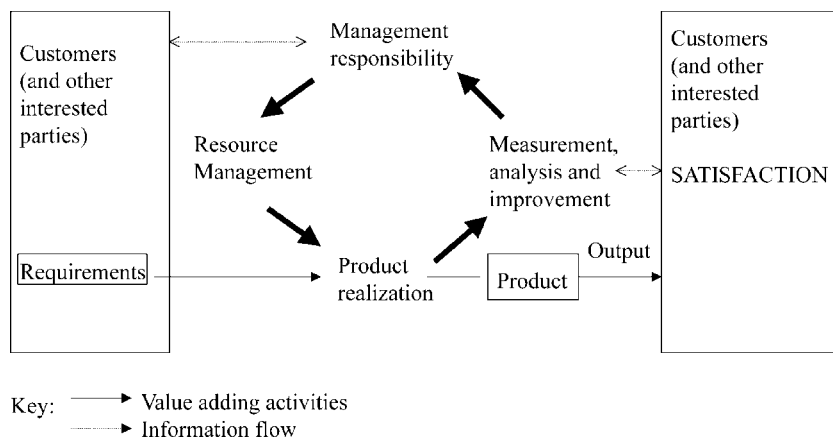

Fig. 3 represents ISO's view of the quality system. ISO 9000 emphasizes the criticality of the role of top management for the achievement of quality products and processes. This role is described in detail in the document. Besides the emphasis on system and process, ISO highlights the importance of culture/environment. "Through leadership and actions, top management can create an environment where people are fully involved and in which a quality management system can operate effectively."

The Malcolm Baldrige quality award represents a still higher standard.^[7] It is very comprehensive, involving all

aspects of the business. It's core values and concepts are similar to those of ISO 9000. The categories and point values are given in Table 2.

Note the heavy weighting given to results. The winners of this award generally score in the 700's. It provides a useful tool for a self-assessment, a benchmarking tool, even if your organization does not want to go to the expense of applying for the award.

After reviewing model quality systems like ISO, Malcolm Baldrige, or the European Quality Award, it is evident that cGMPs fall short of being a true quality system. They lack many elements common to these quality models such as leadership, planning, process orientation, and continuous improvement. A corollary concern is sometimes expressed that the pharmaceutical business is so regulated that a best practice quality system like ISO is not sufficient. However, a central tenant in all good quality systems is a customer focus, continuously evaluating customer needs/requirements and satisfaction. Companies that truly understand and put in practice these quality systems will have no trouble meeting regulatory customer requirements.

**Fig. 3** Continual improvement of the quality management system.

QUALITY PLANNING PROCESS

In order to continuously improve the quality system, there must be in place a quality planning process. The purpose of this process is:

- To evaluate the current quality system relative to the desired quality system, both short and long term.
- To develop action plans and allocate resources so that the desired improvements in the quality system are achieved.
- To monitor and measure performance against the plan.
- To adjust the plan as needed.

A diagram of the quality planning process is shown in Fig. 4. This planning process represents the first four steps in the continuous improvement cycle (Fig. 5), discussed in the “The Quality Improvement Process.”

The quality planning process begins with setting competitive standards, with creating the vision of excellence that ensures success and that focuses and motivates all employees. An important part of creating this picture of the desired future is benchmarking; both business and quality targets and the processes that enable the achievement of these targets. One can benchmark best internal performance and even other pharmaceutical plants/companies. However, some of the best quality practices are not found in the pharmaceutical industry, but are found in other industries. The books and magazines published by the American Society for Quality are a good source of best quality practices. One can also learn much from the Malcolm Baldrige winners.

The second step is to honestly and accurately assess one's current state. The performance of process assessments has proven to be an effective tool for doing this.^[8] This method differs significantly from the traditional compliance audit. It focuses on efficiency as well as effectiveness in achieving standards. It looks beyond observations or symptoms for root causes. It focuses on the quality of the processes and their outputs. It borrows from the Malcolm Baldrige award the evaluation of:

1. Approach (process design and process ownership).
2. Deployment (training, resource allocation, and integration among departments and with other processes).
3. Results (continuous improvement of performance metrics).

Once the desired end-point is determined and the current situation is assessed, a gap analysis is completed and objectives are set to close the gaps. An important step in the process is the prioritization of objectives, based on balancing available resources with risks. The development of the plan is ideally a participative one, involving the maximum number of people. After the plan is developed, personal and team performance objectives need to be aligned with the goals of the plan. Finally, it is necessary to integrate the quality plan with the overall business plan.

“What gets measured gets done.” The health of the quality system and the effectiveness of the quality plan need to be monitored. Therefore selecting the right set of quality metrics is important.^[9,10] Traditionally quality costs are broken down into preventive, appraisal, internal failure, and external failure costs. A commonly used

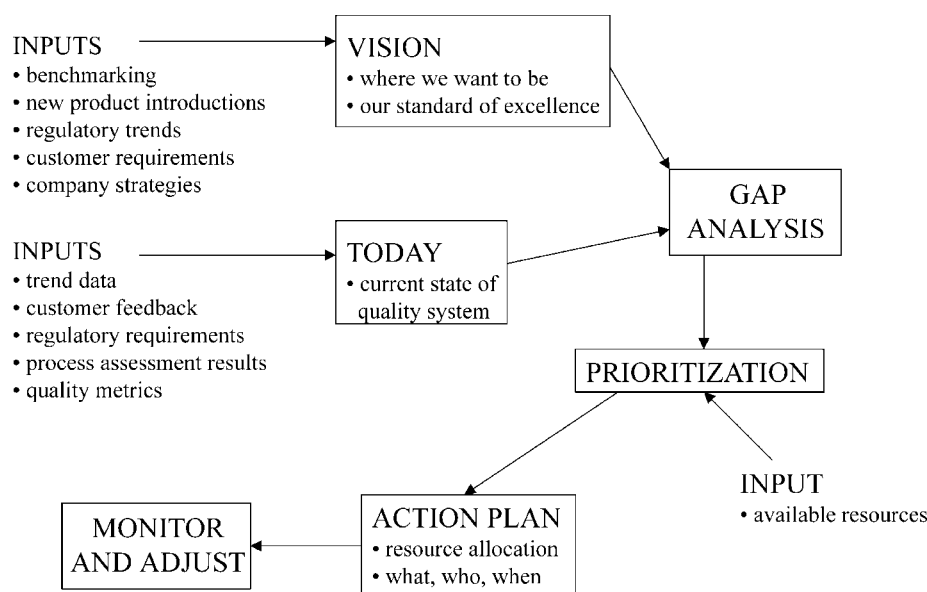

Fig. 4 The planning process.

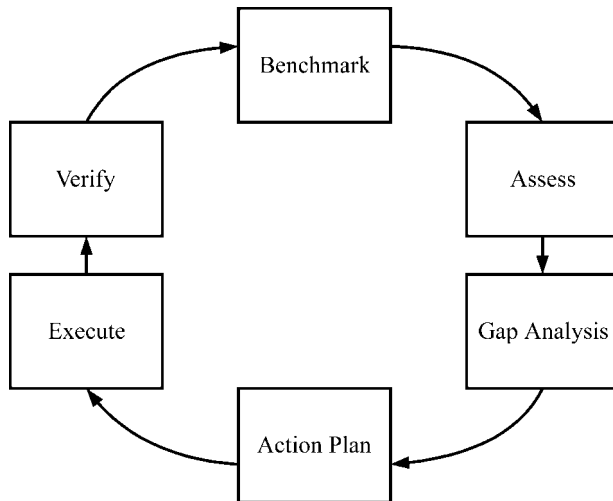

Fig. 5 The continuous improvement process.

indirect measure of internal failure costs is not-right-first time. Cycle time is another useful indirect measure of quality. Process quality can be measured.^[8] Processes can be rated on a 1–5 scale where:

1. Process and ownership not defined, personnel are not trained, results show process is ineffective.
2. Process and ownership are defined, personnel are trained, process metrics are in place; but process is not always followed and results need improvement to meet minimum standards.
3. Process is consistently followed and results are satisfactory.
4. Process has been continuously improved in effectiveness, efficiency, and cycle time over the past 2 yr. It is appropriately fail-safe and mistake proof.
5. Based on benchmarking process is considered world class.

For each key process there should be a set of metrics. These process metrics could consist of process cost, effectiveness, right-first-time, and customer satisfaction. Examples of metrics for the change control process are:

- Cycle time.
- Changes made without an adverse product impact (%).
- Number of changes successfully implemented per year.
- Customer/employee satisfaction with change control process.
- Completeness of documentation.

The quality metrics need to be reported to management so that they can determine the health of the quality system

and take whatever action is necessary to improve it. The importance of metrics and their selection cannot be over emphasized. “People need an assessment of some kind to give them a sense of where they really are. They need to know the starting point from which they will proceed in improving the quality of their contribution.”^[11]

THE QUALITY IMPROVEMENT PROCESS

The link between quality planning and quality improvement is execution. The continuous improvement cycle (Fig. 5) starts with benchmarking and internal assessment to arrive at a gap analysis. From the gap analysis an action plan with assigned leadership, resources, timelines, and metrics is developed. From this quality plan, the plant’s human resources must successfully execute the plan for improvement to occur. It is the leadership’s responsibility to assure that the plan is “do-able,” appropriate and adequate resources are assigned, and that the culture of the plant supports change. This starts with the project leaders who must have not only the technical skills, but also the project management and people skills to accomplish the project. Training in the proper skills to lead a quality improvement project is available from many consulting firms promoting the concept of “Six-Sigma.” People trained in these skills are often called “Black Belts.”

Once the project has been completed and determined to be successful by appropriate metrics, it is time for management to reinforce the culture of continuous improvement through appropriate team rewards and recognition. It is best practice for the plant to reinvest some of the saving from any improvement in other improvement opportunities.

RESPONSIBILITIES IN THE QUALITY SYSTEM

Quality must be every employee’s responsibility. The quality department will never succeed in forcing quality into products and processes. Instead, the plant’s management team must, by their actions, hold each employee accountable for the quality of their work. Management must, in turn, assure that all employees understand the requirements, have the necessary skills, and have adequate time and resources to perform their job.

The specific responsibilities of some key management personnel are:

1. Plant manager, the champion of quality
 - Establish the expectation that quality is everyone’s responsibility by his leadership actions.

- Establish in the total organization a quality culture of customer focus, continuous improvement, and accountability for quality.
- Assure appropriate resources are provided for quality and compliance.
- Make quality planning a prime component of the plant's planning process.
- Recognize and reward quality performance.

2. Quality manager

- Own the system/process assessment process.
- Facilitate system/process design and improvement teams.
- Assure the organization is adapting to changes in the external environment.
- Develop the needed quality knowledge and skills within the organization.
- Interpret the compliance and customer requirements.
- Assure quality/compliance accountabilities are fulfilled by organization.

3. Production manager

- Assure processes are performed, measured, controlled, and documented as designed.
- Provide opportunity for the workforce to identify and implement quality and efficiency improvements of processes.
- Identify root causes of failures and implement preventive actions.

4. Engineering manager

- Provide an infrastructure that is appropriate, calibrated, validated, controlled, documented, and maintained.
- Provide technical support to the improvement process.

5. All employees

- Focus on the customer, internal, and external.
- Continuously improve one's process.
- Be accountable for the quality of one's work.

- Sets direction.
- Creates customer focus.
- Establishes clear and visible values.
- Sets high expectations.
- Creates strategies and systems to achieve excellence, stimulate innovation, build knowledge and capabilities.
- Inspires and motivates the workforce.
- Encourages all employees to contribute, to develop and learn, to be innovative, and to be creative.

To put these leadership goals into practice, we have established Quality Management Teams (QMT) in each of our plants.^[12] The QMT consists of the complete plant management team—quality, production, engineering, technical support, human resources, and finance. The plant managers chair the QMT to symbolize their responsibility for quality and because they have the power to assure all employees follow the quality principles. The purpose of the QMT is:

- To provide plant management with a forum to exercise their responsibility for the establishment and maintenance of an adequate and effective quality system.
- To foster a partnership to manage continuous improvement in quality by focusing on processes, people, and culture.
- To jointly plan for improvement of the quality dimensions of business performance and to own the quality plan.

The QMTs meet monthly for at least an hour and quarterly for a more extended time to perform a complete review of the quality system and quality plan.

SUMMARY

Quality is fundamentally about customer focus. Both the pharmaceutical industry and the FDA have this in common; their customer is the patient. While quality control and quality assurance are important, best quality practice today emphasizes the management of the quality system. The quality system consists of important processes, highly skilled people, and an empowering/motivating culture. Training of personnel at all levels must be a priority for management. The recommended model of a quality system is ISO 9000 with the specific requirements of GMPs added. Continuous improvement of the quality system is assured by having an effective quality planning process. All employees must take responsibility for the quality of their work. A critical but difficult process is communication. Management must provide the direction (top–down), listen (bottom–up), and

LEADERSHIP AND MANAGEMENT

We have seen already that both ISO 9000 and the Malcolm Baldrige award criteria give prominence to the role of top management in establishing, maintaining, and improving the quality system. Visionary leadership according to the Malcolm Baldrige award:

encourage cross-functional cooperation. It is clear that quality depends on the leadership of the organization.

RADIOCHEMICAL METHOD OF ANALYSIS

R. Raghavan

Jose C. Joseph

Abbott Laboratories, Abbott Park, Illinois, U.S.A.

INTRODUCTION

In nuclear medicine, drugs containing radioactive metals, metal complexes, and metal conjugates are used for diagnosis and therapy of various diseases. Radioactive materials used as pharmaceuticals are not only small organic and inorganic molecules but are also macromolecules such as monoclonal antibodies and antibody fragments that are attached to radioactive metals. Nuclear medicine has become a \$12 billion medical industry, and more than one-third of the hospitals in the United States currently use radioisotopes for such procedures. It is anticipated that diagnostic procedures in the United States are likely to exceed 20 million by the end of 2000. The successful use of radiochemicals needs a basic understanding of radiation, radioactivity, and the nature and characteristics of instruments to detect and quantitate radiation. This article addresses these applications related to radioactivity and radiochemical methods of measurement.

ATOMIC STRUCTURE, NUCLEAR STABILITY, AND RADIOACTIVITY

Atomic physics describes the structure of atoms in complex mathematical terms of quantum mechanics. However, the model of the atom as described by Niels Bohr in 1913 is very simple, pictorial, and more than adequate for a basic understanding of the phenomenon of radioactivity. Bohr's planetary model of the atom consists of a dense positively charged nucleus surrounded by negatively charged electrons (e) in orbits of well-defined energy states. The nucleus consists of positively charged protons and neutral particles called neutrons. The protons and neutrons are held together by very a strong nuclear force of attraction, effective at very close distances (approximately 10^{-13} cm). These strong forces for each nucleus are computed in terms of binding energy. The electroneutrality of the atom is maintained by the orbital electrons, which are equal in number to that of the protons. This number is called the atomic number, Z . The masses of the atoms (A) and other particles are described in terms of

atomic mass units (amu). The amu is defined as 1/12th the mass of a carbon atom with atomic mass of 12.0000. The properties of these nuclear particles known as nucleons and electron are summarized in Table 1.

Any configuration of protons and neutrons is called a nuclide. There are three nuclides of the element hydrogen with atomic number 1. Some characteristics of the nuclides are listed in Table 2.

The notation A_ZX is used to indicate the nuclide of an element. The three nuclides of hydrogen are called isotopes of hydrogen. Tritium with an N/Z ratio of two is unstable. When the N/Z ratio becomes higher, the nucleus become unstable and results in the disintegration of the nucleus so as to achieve a stable N/Z ratio and therefore a stable nucleus. This process is called radioactive decay. This radioactive process can be spontaneous in some naturally occurring nuclides; then these elements are said to be naturally radioactive. When such instability is brought about by bombarding stable nuclides with high-energy particles, it is called artificial radioactivity. Of nearly 3000 known nuclides of elements, which are either man-made or natural, 287 nuclides of 83 elements are stable; the rest are unstable to varying degrees. The unstable nuclides disintegrate to form stable nuclides with release of energy and nuclear particles. Binding energy and nuclear stability are found to be dependent on the ratio of number of neutrons to protons (N/Z or n/p ratio). To be stable, at least one proton is required. The most stable heavy nuclide is ${}^{209}_{83}X$, with 83 protons and 126 neutrons ($N/Z = 1.5$). In general, when the N/Z ratio is greater than 1.6, the radioactive nuclide readjusts to a stable ratio of N/Z with the release of energy and particles of matter. The three nuclides of hydrogen are called isotopes. Other members of the nuclide family are isobars and isotones. The characteristics of these nuclides are given in Table 3.

Radioactive Decay

Different radioactive species undergo disintegration at different rates. The rate of this decay or activity is characteristic of the individual nuclide and is proportional to the number of radioactive nuclides present at the beginning of this time interval. The proportionality constant

Table 1 Mass, charge, and energies of nucleons and electrons

Particle	Mass (Kg)	Mass (amu)	Charge	Energy ^a (MeV)	Comments

^aEnergy is based on the rest mass of the particle.

is called the decay constant and is denoted by λ . The decay constant is a measure of the probability that a certain radioactive nucleus will disintegrate within a specified time interval. These disintegrations are characteristic of the nuclide and are unaffected by pressure, temperature, concentration, and other physical or chemical properties of the radionuclide. This rate constant is conveniently denoted in terms of $t_{1/2}$, or half-life. The half-life of a radionuclide is the time required for the sample activity to decrease to half its initial value. $t_{1/2}$ is related to rate constant (λ) as follows:

$$\lambda = 0.6932/t_{1/2}$$

In fact, less than 1% will be radioactive in seven half-lives, and after 10 half-lives, greater than 99.9% of the radioactive nuclide will have lost its activity. The half-life refers to that of a pure nuclide. In a sample containing mixtures of disintegrating radionuclides, the total activity is the sum of the separate activities. From a plot of relative activity against time, the individual half-lives can be computed. However, in practice, this can be realized for mixtures containing 3 or <3 nuclides. Other commonly used terms in nuclear medicine and pharmacy are average (mean) half-life, biological half-life, and effective half-life. Average half-life is the mean lifetime of a nuclide, and it is equal to $1.44 \times t_{1/2}$. Biologic half-life, t_b , is the time required

for the body to eliminate half the administered dose by normal biological process of elimination. Effective half-life (t_{eff}) is a measure of how fast the body eliminates the radioactive material by the combination of biological elimination and radioactive decay:

$$1/t_{\text{eff}} = 1/t_b + 1/t_{1/2}$$

Unit of Activity

The fundamental SI unit of activity is the Becquerel (Bq). One Bq is equal to one disintegration per second (dps). Because this is a very small unit, it is more often expressed in kilobecquerels or kBq. However, the older historical unit of activity C_i is normally used for radiopharmaceuticals. The Curie was defined in terms of the number of disintegrations per second of 1 g of ^{226}Ra and is equal to 3.7×10^{10} dps. Other commonly used units are millicurie and microcurie (mCi and μCi). The unit of C_i represents absolute activity (A). However, relative activity R is proportional to the efficiency of the counting device. The device reports in counts per minute.

$R = qA$; q = efficiency quotient. Sometimes specific activity, in terms of radioactivity per unit mass of an element or radiolabeled compound or unit volume of solution is also specified. In these case, the mass or volume should be clearly specified.

Table 2 Configuration of nuclides of hydrogen

Nuclide	No. of protons (Z)	No. of neutrons (N)	N/Z (n/p) ratio	Notation	Nuclear stability
Hydrogen	1	0	0	^1_1H	Stable
Deuterium	1	1	1	^2_1H	Stable
Tritium	1	2	2	^3_1H	Unstable

Table 3 Characteristics of nuclides

Nuclide	Atomic number (Z)	Mass number	Neutron number	Chemical property	Examples
Isotopes	Same	Different	Different	Same	$^{15}_8\text{O}$, $^{16}_8\text{O}$, $^{17}_8\text{O}$, $^{18}_8\text{O}$

Isotones	Different	Different	Same	Different	$^{59}_{26}\text{Fe}$, $^{60}_{27}\text{Co}$, $^{62}_{29}\text{Cu}$, (33 neutrons each)
Isomers	Same	Same	Same	Same	$^{99\text{m}}_{43}\text{Tc}$, and $^{99}_{43}\text{Tc}$. ($^{\text{m}}$) meta stable isomer

Decay Processes

The radioactive decay process involves the emission of radiation, which is dependent on the mode of decay of the particular radionuclide. Radiation resulting from any decay process can be classified as alpha (α), beta (β), gamma rays (γ), and/or other emissions.

α -Particles

Alpha (α)-particles are doubly charged, highly energetic helium nucleus. α -Particles originate in the nuclei of heavier atoms. The emission involving α -Particles is the most efficient process for a radionuclide to attain stability because the nuclide loses both charge and mass. Because α -Particles are very heavy (7400 times of that of an electron) and doubly charged, they attract electrons from the surrounding medium when they pass through a medium. This results in the ionization of the medium. An α -Particle loses energy, slows down, and finally becomes a helium nucleus. In each ionization process, it loses 34 eV per event. For example, a loss of 3.4 MeV of energy causes 100,000 ionization events. These particles travel very short distances, called the range. Because they are extremely efficient in ionizing, they lose energy very rapidly. This range is approximate 4 cm in air and a few thousandths of a centimeter in biological tissues. Because of this tremendous amount of energy transfer, α -Particles can cause extensive damage to organs and tissues when they are exposed to this radiation. Generally, α -Particles arise during the natural decay of elements with a Z value greater than 83. A typical alpha decay process is represented below:

β -Particles

A β -Particle is a high-velocity nucleon ejected out of a decaying nucleus. β -Particles have the rest mass (0.000548 amu) of an electron. If it is negatively charged, it is called a negatron and if positively charged, it is called a positron. In common usage, β -Particle emission refers to

the negatron (β^-) and β^+ -Emission is called positron emission. For example, the decay of $^{32}_{15}\text{P}$ to $^{32}_{15}\text{S}$ results in the emission of β^- , antineutrino, and release of energy. The difference in the masses of the two nuclides, 0.001836 amu (31.965675 for P – 31.9638390 for S), results in the release of energy equivalent to 1.70 MeV. Part of this energy is used up in the ejection of particles, and the remaining is used in the release of antineutrino. Because no other energy is emitted, ^{32}P is called a pure β -Emitter. Sometimes some portion of the energy difference may be retained in the nucleus, and consequently the nuclide resides in a nuclear excited state. The excited nucleus may lose the excess energy and return to the stable ground state in the form of electromagnetic radiation (gamma-rays). β -Particles are emitted with variable energy from zero to the maximum of the difference in energy between the parent and daughter nucleus. The variability in energy arises from the distribution of energy between the β -Particle and the antineutrino.

Negatively charged β -Particles are emitted when the radionuclide has more neutrons than required by the number of protons for stability. Sometimes more than one β -Particle may be emitted. For example, ^{131}I decays with the emission of six β -Particles and 14 γ -Rays of different energies:

Nearly 100% of all these decay processes correspond to β -Particles of energy 0.61 MeV and γ -Radiations of energy 0.364 MeV. The decay to form stable nuclides may involve the formation of many unstable intermediate radionuclides. For example, the decay of $^{127}_{50}\text{Sn}$ to $^{127}_{53}\text{I}$, shown below, involves the formation of a number of intermediate nuclides:

In general, β^- - and β^+ -Particles penetrate deep into the medium; however, they do not cause damage to tissues and

organs. Radionuclides that decay by β -Particle emissions are used very extensively in nuclear medicine for diagnostic and therapeutic applications. Positron-emitting nuclides are used in nuclear medicine for diagnostic purposes. β^+ -Emitting radionuclides are under active study for use in radiotherapy. An example of a decay process involving emissions of positrons follows:

γ -Rays (γ)

During the disintegration of the nucleus, part of the energy is used in the creation of excited-state radionuclide. In the excited state, the nuclide is unstable. The release of energy while the excited nucleus returns to the ground state appears as electromagnetic radiation. These radiations are called γ -Rays. γ -Emission is common when the difference between the excited state and the lowest energy ground state nucleus is greater than 100 keV. Because γ -Emission is electromagnetic radiation, there is no change in the neutron number or mass number or atomic number. Therefore, invariably, γ -Radiation is always preceded by a nuclear decay reaction involving emission of α , β^- , β^+ particles.

γ -Rays are high-energy electromagnetic radiation such as X-Rays with no electrical charge. γ -Rays are different from X-Rays in that they differ with respect to their origin. X-Rays originate from orbital electrons, whereas γ -Rays originate from the decay of a nuclide. The γ -Rays also ionize the medium by striking orbital electrons with high energy and by knocking the electrons out of the atom. These ejected electrons cause secondary ionization referred to as indirect ionization. The degree of penetration of γ -Rays is extremely high. There are at least seven different processes by which γ -Rays can interact with matter. However, the processes associated with γ -Ray interaction or production, which are pharmaceutically relevant, are electron capture, isomeric transition, and internal conversion. These are briefly discussed below.

Electron capture is a decay process in which an orbital electron loses energy and becomes absorbed into the nucleus. As a result, outer-shell electrons jump to fill the inner-shell vacancy resulting in an electron orbit reshuffling. This process results in the release of X-Rays, and these electrons are subsequently absorbed and result in the release of weakly bound orbital electrons. These are called Auger electrons. When the decay process involves positron emission, it is almost always followed by electron capture. As a result of nuclear reaction, an excited radionuclide (with energy >100 keV) loses energy by de-excitation:

More often, these occur in multiple steps with the release of γ -Ray photons of multiple energy. Thus, the resulting γ -Ray spectrum is unique to the decaying radionuclide; this uniqueness, therefore, is used to identify the unknown nuclide. γ -Rays with no mass and charge can penetrate into matter and bring about other chemical reactions in the system. γ -Rays are widely used in nuclear medicine.

An excited radionuclide may remain in several excited states before reaching ground state. However, transitions can occur within these excited states with the emission of γ -Rays. These transitions are called isomeric transitions. When these isomeric transitions are significantly long-lived, these are called metastable states.

An example of the decay process is shown below. (\nearrow — increase in Z, \nwarrow — (left arrow) decrease in Z)

A process alternative to isomeric transition is called internal conversion (IC). In some cases, the γ -energy is absorbed by a K-shell (inner) electron. This electron is ejected out with lower energy. This ejected electron is the internal conversion electron, and the process is called internal conversion. Some diagnostic and therapeutic radionuclides with corresponding half-lives are given below.

Diagnostic radionuclides: ($t_{1/2}$ in units as indicated are given in parentheses.) $t_{1/2}$ hours: ^{67}Cu (62.0); ^{67}Ga (78.3); ^{90}Y (64.1); ^{117}In (67.9); ^{99m}Tc (6); ^{201}Tl (72) { β^- -particles}- t min; ^{11}C (20.4); ^{13}N (10.1); ^{15}O (2.0); ^{18}F (1.9); ^{68}Ga (68.0); and ^{82}Rb (1.25) { β^+ }.

Therapeutic radionuclides: $t_{1/2}$ days: ^{32}P (14.3); ^{47}Sc (3.4); ^{67}Cu (2.6); ^{64}Cu (0.5); ^{90}Y (2.7); ^{105}Rh (1.5); ^{111}Ag (7.5); ^{117m}Sn (13.6); ^{131}I (8.0); ^{149}Pm (2.2); ^{153}Sm (1.9); ^{166}Ho (1.1); ^{177}Lu (6.7); ^{186}Re (3.8); ^{188}Re (0.7).

RADIATION DETECTION AND MEASUREMENT

Interaction of Radiation with Matter, Ionization Chamber, and GM Counters

The detection and quantitation of nuclear radiation are based on its interaction with material contained in the

detector. Ionization of the gas particles in the medium and scattering are the two most common types of interaction of radiation with matter. Radiation causes darkening of photographic emulsion, ionization of a gas or a mixture of gases, or fluorescent scintillation. In radiology, exposure and observation of the photographic film are most commonly used. When α -Particles with high kinetic energies impinge on gases enclosed in a chamber, they produce approximately 40,000 ($\pm 10,000$) ion pairs per cm. The range of α -particles is short (approximately 6 cm in air and 2 μM in lead); β -Particles have longer and irregular paths and produce approximately 100–700 ion pairs per cm. A typical ionization chamber, shown in Fig. 1, consists of a sealed tube containing helium, neon, or gas–air mixtures placed in a space between two electrodes. The incoming particles create ion pairs; the ions are separated and collected at the electrodes of opposite charge. Electrons are collected at the anode. The number of such ions collected at each electrode is also a function of the applied voltage across the electrodes. If the response is measured in terms of pulse height (proportional to the number of electrons collected), a plot of this value against applied voltage will exhibit a characteristic response as given in Fig. 2. The different regions in Fig. 2 are explained below. Region I is called the recombination region. In this region, ion pairs produced increase linearly as a function of applied voltage (<100 V) as recombination is proportionately decreased. This is not a useful region for measurement. In region II (100–400 V), pulse height attains a plateau because all ions formed are collected. This region is used in ionization chambers to measure energies of γ -Rays and X-Rays. This region is also used for identification of α - and β -Particles because the height at which plateau occurs is characteristic of the nature of the particle. Dose meters and dose rate meters, which measure high-intensity radiation fields,

Fig. 1 Block diagram of a simple air ionization chamber. Electrons are attracted to the positive plate, and positive ions go to the negative plate.

operate in this region. In region III (400–800 V), the number of pulses produced is proportional to the intensity of radiation. The size of the pulses counted gives a measure of the primary ionization produced. In this region, the primary electrons are accelerated with high gain in energy. This high energy causes additional secondary electrons to be generated as a result of interaction with gases in the ionization chamber. These secondary electrons cause further ionization. The net effect is pulse amplification; the size of the amplification is of the order of 100–10,000 times that of the size of the ions initially produced in the ionization chamber.

In Fig. 2, the two response plots correspond to two particles of different energy. Ionization chambers operate in this region.

Region IV (applied voltage 800–1000 V) is limited proportional region and is not important for purposes of detection. When the applied voltage is between 1000 and 1500 V, the size of the pulse is no longer proportional to the initiating event. However, each pulse corresponds to a single event. The counters that operate in this region are called Geiger–Mueller counters or GM counters. The GM counters are very sensitive. Because of the high gain involved, these are used primarily in regions where the radioactivity is of very low intensity, (e.g., radioactive contamination). The readings are given in milli-, micro-, or Roentgens/h or in counts per minute. In the GM counter, ionization produced spreads to the entire gas. Therefore, the counter may not respond to a succeeding second incoming pulse before a recovery time of approximately 100–300 μs . This dead time for recovery is unusually high compared with the dead time for the proportional counter, which is approximately 1 μs . Secondly, because a fixed amount of gas is present in the chamber, the purity of the gas in the chamber decreases. Therefore, the GM counter has to be calibrated frequently, using standard ^{226}Ra or ^{137}Cs sources

Fig. 2 Pulse height versus applied voltage response.

per Nuclear Regulatory Commission (NRC) requirements. Above an applied voltage of 1500 V, continuous discharge occurs, and this is not useful for any measurement.

Scintillation Detectors

When radiation interacts with certain substances called fluors or phosphors, it produces a flash of light called scintillation. The scintillation is then detected using a sensing element, amplified, sorted, and recorded by counting. The scintillation-detecting instruments include well counters, scanners, thyroid probes, and scintillation cameras called Auger cameras. In addition, all these instruments consist of a collimator (excluding well counters), photomultipliers, a high-voltage power supply, an amplifier, a gain control unit, a pulse height analyzer, and instruments or computers for appropriate display modes. The scintillation cameras also contain coordinate-positioning (x,y) circuits.

Solid-State Detectors

These detectors are made of semiconducting materials. In these detectors, solid-state electrodes are made from Li doped with Si or Ge. The resolution is approximately 1–2 keV for 1 MeV γ -Rays and sometimes provides a greater than 10-fold improvement over NaI (Tl) scintillation detectors, described below. These are commercially available and more often used in research-grade instruments.

A brief review of scintillation phosphors and their uses are given in Table 4.

Liquid Scintillators

The sample radionuclide is dissolved in a liquid scintillator called the scintillation cocktail. It consists of two principal components. The first is a primary solvent such as toluene, xylene, or 1,2,4-Trimethylbenzene (pseudocumene). The second component is the fluor solute, 2,5-Diphenyloxazole (PPO) that emits UV light at ~ 380 nm. The cocktail may also contain one or more the following:

- A secondary solvent such as dioxane to improve solubility of aqueous samples or surfactants such as sodium dodecylbenzenesulfonate as emulsifier
- A secondary scintillator to shift the wavelength of photons emitted (~ 380 nm) to the wavelength response of some photomultiplier tubes (PMT, ~ 420 nm)
- One or more adjuvants for purposes of suspending or solubilizing biological tissues.

A brief description of other components of scintillation detectors (generally applicable to liquid scintillators also) is given below.

Photomultiplier (PM) tubes

The PM tube has a light-sensitive electrode called the photocathode. It emits electrons when photons strike it. The electrons are then accelerated from the photocathode to the anode of PM tube by the application of approximately 1000 V in steps of approximately 100 V by a series of electrodes called the dynodes. In the PM tube, secondary electrons are produced, resulting in pulses of 10^5 to 10^8 electrons. Typically a phototube with 10 dynodes delivers approximately 4^{10} electrons. This gain or amplification is dependent on the dynode voltages.

Preamplifier

Even though such a large number of secondary electrons are generated, these are not adequate to generate enough current. The voltage pulse is amplified by a factor of 4–5 by the preamplifier without loss of power. The preamplifier also provides the driving force necessary to prevent loss in the several feet of connecting cables.

Linear amplifier

The pulses received from preamplifier have wide variation in energies of the particles. The gain in the amplifier is of the order of 8000 such that a 1-mV signal is amplified to approximately 8 V while still maintaining the proportionality of the energy delivered by the particle (more often γ -Ray) to the detectors. The amplified pulse is then delivered to pulse height analyzer.

Pulse height analyzers (PHA)

The pulses that emerge from the amplifier usually have different amplitudes owing to differences in energies. These analyzers are essentially energy sorters. Single-channel PHAs count pulses of a given amplitude, whereas multichannel analyzers (MCAs) scan whole energy range and record the pulses in each channel. For example, by using an MCA, γ -Ray spectrum can be recorded and, thus, these instruments that use MCAs are called γ -Ray spectrometers. MCAs may have as many as 4000 channels.

X-Y-positioning circuits

These are unique to scintillation cameras, known as Auger cameras, used in nuclear medicine studies. Approximately 19–91 PMTs are mounted on a Na(Tl) crystal used in the camera. These crystals are typically thick. The number of PMTs, which are optically coupled to the back of the crystal, is determined by the size and shape of the crystal. A maximum amount of light will be received by the PMT nearest to the point of interaction compared with the other PMTs, which are positioned differently. The amount of light received in these PMTs is proportional to the solid

Table 4 Scintillation phosphors and their uses

Particle detected	Phosphors used	Characteristics/comments
Alpha (α)	Thin sheet of plastic scintillator or zinc sulfide embedded in a transparent tape	Phosphors are wrapped in very thin aluminized mylar foil to exclude light. α -Particles, because of low penetrating power, lose all their energy to scintillators. β - and γ -Particles produce only smaller pulses and by adjustment of appropriate setting of the discriminator, α -Particles alone can be counted.
Beta (β)	Single crystals of anthracene, <i>trans</i> -stilbene are commonly used. Sometimes naphthalene doped with anthracene can also be used.	For β -Particle counting, especially low-energy particles from ^{14}C and tritium, liquid scintillators are commonly used (see discussion below on liquid scintillators).
Gamma (γ)	Sodium iodide doped with thallium iodide are used [NaI(Tl)]; thallium, which is present at 0.1–0.4% of sodium emits 420 nm scintillations. This phosphor is very efficient in absorbing γ radiation because of high atomic number of iodine and high density of sodium iodide.	Sodium iodide is hermetically sealed. It is normally used in well counters. A typical well counter used in laboratory and that used in cameras in nuclear medicine are show in Figs. 3 and 4.

angle subtended by the PMT. Therefore, X – Y -positioning of the camera has to be controlled and known so that X – Y -coordinate of the γ -Ray interaction can be assessed accurately. These data are stored in a computer and then processed or recorded on Polaroid or X-Ray films.

Efficiency of detection in scintillation detectors

In gas-filled as well as scintillation detectors, the observed count rate is typically less than the actual decay rate of the radionuclide. The efficiency of detection may differ from particle to particle under identical conditions using the same type of detector. The factors that affect the efficiency of detection are operating voltage, resolving time, geometry of the instrument used in relation to the position of the sample with respect to the detector, scaler, energy resolution, absorption by cells, and sometimes constituents of the sample itself. For example, the scintillation cocktail sometimes reduces counts considerably. This effect is known as quenching. For accurate measurements of radioactivity, appropriate correction for quenching is required.

Frequent calibration of the instruments with the use of appropriate standards is required to make suitable allowances for decreases in the efficiency of the instruments. Such calibration standards are available from the National Institute of Standards and Technology (NIST). Other sources traceable to NIST standards through active program of participation in comparison measurements also provide such standards. The United States Pharmacopeia (USP) also provides nuclear decay data for new calibration standard. USP 24 lists $t_{1/2}$, energy of photons, and number of

photons per disintegrations, for the following radionuclide standards: ^{137}Cs , $^{137\text{m}}\text{Ba}$, ^{22}Na , ^{60}Co , ^{57}Co , ^{54}Mn , ^{109}Cd , ^{109}Ag , and ^{129}I .

Tomographic Imagers

Tomography is a process in which three-dimensional images are constructed using a large number of two-dimensional slices of images from an object. Computed tomography uses rigorous mathematical algorithms to reconstruct these images. When radionuclide emissions are used, it is called emission tomography. Two common techniques are now used to obtain images using emission tomography, namely, single photon emission computed tomography (SPECT) and positron emission tomography (PET). In SPECT, γ -Emitting nuclides are used, whereas in PET, positron-emitting nuclides are used. In the SPECT system, an object is photographed using many Auger cameras at a number of small angles (between 3 and 10°) around the object. The total span may be between 0 and 180° or between 0 and 360°. Because the rotating cameras provide two-dimensional digital images, these are stored as 64 × 64 matrix (for 180° span) or as 128 × 128 matrix (for 360° span) digital information. The Auger cameras use NaI (Tl) crystals in the detector heads. In PET, positron-emitting radionuclides are used. Each positron emitted from these radionuclides travels through tissues, deposits energy, and finally is annihilated by interaction with an electron. The annihilation results in the formation of two photons traveling in opposite directions (180° apart) with energy of 0.511 MeV. Two Auger cameras are placed 180°

Fig. 3 A typical well counter used for measurement of gamma rays.

apart but at the same distance from the object. Each camera detects a photon at the same time. By appropriately moving cameras in pairs, the data are collected over many angles and stored in 64×64 or 128×128 matrix. Thus, this electronic collimation brought about by simultaneous detection increases sensitivity and reduces the need for use of collimators as in SPECT. Additional advantages of PET include easy availability of radionuclides with short half-lives of isotopes of elements commonly found in organic molecules (such as F, N, C, and O). (See USP 24 for additional details of requirements for radiopharmaceuticals for PET.)

ANALYSIS OF RADIOCHEMICALS

Radiochemical methods of analysis are considerably more sensitive than other chemical methods. Most spectral methods can quantitate at the parts-per-million (ppm) level, whereas atomic absorption and some HPLC methods with UV, fluorescence, and electrochemical methods can quantitate at the parts-per-billion (ppb) levels. By controlling the specific activity levels, it is possible to attain quantitation levels lower than ppb levels of elements by radiochemical analyses. Radiochemical

analysis, in most cases, can be done without separation of the analyte. Radionuclides are identified based on the characteristic decay and the energy of the particles as

Fig. 4 A typical well counter used in nuclear medicine.

described in detection procedures presented above. Radiochemical methods of analysis include tracer methods, activation analysis, and radioimmunoassay techniques.

Tracers and Tracer Methods of Analysis

Radiochemical tracers or radiotracers are compounds labeled with radioisotopes. For tracer methods, the compound to be measured or a suitable reagent is radiolabeled. A measurement of the redistribution of tracer within such a sample–reagent reaction system provides the required quantitative analytical information. Major advantages of tracer methods are high sensitivity, simplicity, and speed. Radiotracers are more commonly used for following mechanisms of biological and/or chemical processes or if there is need to eliminate complicated separation procedures, especially in biological processes.

Isotopic dilution analysis

In isotope dilution analysis, a known amount of radiolabeled compound with known specific activity is spiked to a known amount of an unknown mixture containing the same compound made up of stable isotopes. Then, the components of the radiotracer-diluted samples are mixed thoroughly to form a homogeneous mixture. This isotopically diluted mixture, with known levels of dilution, is then suitably treated to isolate a small amount of the desired constituent. The radioactive isotope content of the isolated portion is determined by measuring its specific activity. From the specific activities of the tracer before and after dilution, the concentration of the component in the mixture can then be calculated. The major advantage is that these isolation procedures need not be quantitative; however, it is necessary that the compound isolated should be pure enough for an activity determination. Isotope dilution analyses are used for determination of inorganic trace elements and for the determination of organic compounds in biological systems. If separations are required and the radioisotope concentration is not adequate to bring about separation, dilutions can be accomplished by using a nonradioactive compound (or carrier) with similar chemical behavior. For example, if radio strontium is to be precipitated and it is in low amounts such that it cannot be quantitatively precipitated, it can be coprecipitated along with a calcium salt by the addition of calcium before precipitation. An alternative procedure to isotope dilution, reverse or inverse isotope dilution, can be used to determine the quantity of radioactive compound by dilution with an inactive compound. This procedure is applicable when a

system contains an unknown amount of isotopically labeled substance of known specific activity.

Radioisotope exchange

For understanding mechanisms and kinetics of organic or biological reactions, nonradioactive atoms in molecules or ions are allowed to exchange with appropriate radio-labeled compound. After chemical exchange between a labeled compound and the test sample (the chemical form of the element being different in the two solutions, e.g., iodine in CH_3I vs $^{131}\text{I}^-$ in labeled sodium iodide), the specific activity of the element becomes the same in the sample and reagent. A measured decrease in the activity of the reagent or increase in the activity of the sample can then be related to the amount of element present in the sample. Isotopic exchange methods of analysis are very sensitive, rapid, and specific. Isotopic exchange plays a very important role in pharmacokinetic studies. For example, a drug molecule may be labeled with tritium to follow the drug distribution. Exchange of tritium with an unlabeled compound or with a water molecule in the vicinity may lead to erroneous interpretation of the drug distribution if suitable precautions are not taken to avoid potential isotopic exchange reactions.

Radiotracers as radiopharmaceuticals:

Methods for radiopharmaceutical analysis

When radiolabeled compounds (radiotracers) are used for diagnostic and therapeutic purposes, it is called a radiopharmaceutical. A radiopharmaceutical should be easily produced, inexpensive, readily available, have relatively short halflife, and preferably should be a γ -Emitter with an energy between 30 and 300 keV. Such a γ -Emitting nuclide should invariably decay by electron capture or isomeric transition. When positron-emitting nuclides are used, they must have specific localization in the desired organ or tissue and should not result in undue radiation exposure. Radiotracers, used as pharmaceuticals, are produced in one of two ways: either as a product of nuclear fission reactions or as a product of nuclear reactions induced by high-energy accelerator particles or neutrons. Particle accelerators are instruments that cause nuclear reactions by bombarding target nuclides with highly accelerated and energized particles such as protons, deuterons, and electrons. For production of radiopharmaceuticals, on-site accelerators called cyclotrons are used. For production of positron-emitting radionuclides linear accelerators are used. Readily transportable instruments, which serve as sources for short-lived radionuclides, are called generators. Typically, in a generator, a long-lived parent nuclide is allowed to decay to a short-lived daughter

radionuclide. Using differences in chemical properties, the daughter nuclide is separated from the parent. Typical pharmaceutically relevant radionuclides and their sources are summarized in Table 5.

A radiopharmaceutical is a radioactive chemical used as a pharmaceutical. Therefore, as pharmaceuticals, they should have proper ionic strength, pH, isotonicity, and osmolarity. In addition to chemical purity, radionuclide purity and radiochemical purity also have to be demonstrated. The radionuclide purity refers to the ratio of the amount of radioactivity corresponding to that of desired radionuclide to the total amount of radioactivity owing to other isotopes and other isotopic impurities. Radionuclide purity is determined by measuring half-lives and other characteristics of radiation of the radionuclide. Radiochemical purity refers to the fraction of total radioactivity in the desired form. Radiochemical impurities are general chemical impurities formed by the chemical as a result of decomposition of the chemical entity, whereas all the resulting impurities may still be radioactive. Potential decomposition pathways are the same as for any other pharmaceutical. Examples include acid and base hydrolysis products, oxidized and reduced species, additional radiolysis products, and photochemical and thermal decomposition products of the chemical. For example in many ^{99m}Tc -labeled complexes, free unreacted $^{99m}\text{TcO}_4^-$ and hydrolyzed ^{99m}Tc are radiochemical impurities. A number of analytical methods can be used to detect and determine radiochemical impurities. For example, when separating the impurities from radiochemical compound of interest using HPLC, if a radiochemical detector is used, all the radioactive impurities that are separated can be quantitated, and radiochemical purity can be ascertained. These include but are not limited to distillation, precipitation, paper, thin layer, gel chromatography, HPLC, ion exchange, solvent extraction, and other separation and purification techniques. The techniques and principles of these

techniques are the same as for any other pharmaceutical. Thus, these techniques are not addressed here.

Activation Analysis

Activation analysis is a process in which a target trace element in a sample matrix is irradiated with particles in a nuclear reactor. As a result, an activated radionuclide is formed. The characteristic particles or γ -Rays emitted are used for qualitative identification and, more often, for quantitative measurement. The most common activation analysis is neutron activation analysis (NAA). In this technique, a sample containing the element is irradiated with neutrons in a reactor. After irradiation, γ -Emissions ensue from the decaying radionuclide. These are quantitated by using appropriate semiconductor radiation detectors. Detecting γ -Rays of a specific energy identifies the radionuclide. These particular energy values correspond to unique energies characteristic of the decaying radionuclides. For example, when ^{24}Na decays to ^{24}Mg , the γ -Rays released have unique energies of 1.268 and 2.754 MeV. A plot of γ -Ray counts versus energy yields a γ -Ray spectrum; the area under the curve is proportional to the radioactivity of the sample. The rate at which γ -Rays are emitted is proportional to the concentration of the radionuclide. When a large number of elements in a single sample matrix are analyzed using appropriate instruments for quantitation, without separation of the elements, it is called instrumental neutron activation analysis. When there is spectral interference in the sample matrix and if chemical separation is carried out to isolate the element, it is called radiochemical neutron activation analysis. When other charged particles are generated for analysis by activation, it is called charged particle activation analysis (CPAA). CPAA is applied to the determination of elemental concentration in surface layers.

All methods of activation analysis are very accurate and sensitive, and a precision of approximately 2% RSD is easily attainable. Detection limits in parts per billion or lower, depending on the element and sample matrix, are

Table 5 Examples of radionuclides and their production mode

Production mode →	Reactor	Accelerator	Generator
Radionuclides Produced → (some examples)	^{99}Mo , ^{131}I , ^{137}Cs , ^{133}Xe , ^{32}P , ^{51}Cr , ^{125}I , ^{135m}Ba , ^{195m}Pt .	^{123}I , ^{57}Co , ^{67}Ga , ^{201}Tl , ^{111}In , ^{127}Xe , ^{81}Rb . The following positron generating nuclides are produced on site: ^{11}C , ^{13}N , ^{15}O , ^{18}F ;	^{99}Mo to ^{99m}Tc , to $^{99}\text{Tc}^a$, ^{113}Sn to ^{113m}In , to ^{113}In , ^{87}Y to ^{87m}Sr , ^{81}Rb to ^{81m}Kr , to ^{81}Kr , ^{195m}Hg to ^{195m}Au , to ^{195}Au ; other elements used for generator reactions include ^{68}Ge , ^{62}Zn , ^{137}CS , and ^{82}Sr .

^aDecay as indicated below: parent to daughter to granddaughter.

easily attainable. As many as 60 different elements that can form radionuclide can be analyzed using NAA. NAA finds wide application in a number of other fields, and these are summarized in Table 6.

Radioimmunoassay

Radioimmunoassay (RIA) is a technique based on the formation of antigen–antibody complex. This technique essentially involves the application of isotope dilution analysis. An antigen is typically a protein of molecular weight greater than 10,000 that stimulates the production of antibody in an animal body. The antigen subsequently binds with the antibody. Antigen is usually measured in the patient's sample, and the antigen becomes the analyte. To an antibody, a mixture of labeled and unlabeled antigen is added in excess such that the quantity of antibody needed to bind is allowed to be insufficient. As a result, both types of antigen compete with the limited amount of antibody in the sample. The reaction in an RIA mixture can be described as follows.

k_1 and k_2 are rate constants; equilibrium constant $K = k_1/k_2$.

To a constant amount of labeled antigen and antibody, increasing amounts of unlabeled antibody are added. The initial amount added is still in excess of the antibody needed for binding. As a result of competing reactions of the labeled and unlabeled antigen, the greater the concentration of the unlabeled antigen added, the less is the amount of bound labeled complex (Ag^*-Ab complex) and hence greater is the free (unbound) antigen. After

incubation to equilibrium at a specified temperature and time, unique to the system, separation of the free labeled Ag^* , the fraction of the bound labeled antigen is determined by measuring the activity of the radioactive nuclide. By plotting the percent of bound labeled antigen versus the concentration of antigen added, the concentration of the unknown antigen can be determined. Several radionuclides such as ^{14}C , ^3H , ^{131}I , ^{32}P , ^{75}Se , ^{59}Fe , ^{99}Mo , and ^{57}Co have been used for RIA. However, ^{125}I is the most commonly used radionuclide for RIA. The earliest method of separation included electrophoresis and chromatography. However, today RIA kits are marketed by commercial manufacturers with detailed description of the principles of the method, methods of use, sensitivity, precision, and limitations of use for specific uses. The RIA methods are very rapid, sensitive, specific, and inexpensive, especially for large biological samples in complex sample matrices.

The RIA technique is applied in assays of hormones, steroids, peptides, aminoglycosides such as tobramycin and gentamycin, insulin, many immunoglobulins, different types of viral hepatitis, plasma catecholamines, angiotension-converting enzymes, many vitamins including vitamin B_{12} , human growth hormones, many folate derivatives, and others. Many commercially available RIA kits, unique to each kit, contain series of standards with known concentrations of unlabeled antigen, a vial of suitable labeled antigen, a vial of antibody solution, and appropriate precipitants or other analytical aides.

RADIATION SAFETY

When radiation energy is absorbed by tissues, depending on the dose received, rupture of chemical bonds occurs that causes damage to cells and tissues. Such damage may not be clinically apparent even for years if the absorbed

Table 6 Application of neutron activation analysis

Field of application	Typical application
Geology	Characterization of elemental deposition or formation
Environmental science	Atmosphere, soil, and water pollution
Industrial engineering	Corrosional and frictional effects
Agriculture	Nutrient deficiency
Chemical studies	Contamination, characterization of reference standards, surface effects
Forensic science	Sample identification, correlation of samples to crime scenes

dose is small. Radiation damage is measured in terms of absorbed dose. Dose is defined as the energy imparted to a material per unit mass. The SI unit of dose is called Gray, or Gy (joules/Kg). The traditional unit is rad. One Gy = 100 rads. However, the effectiveness of all radiations is not the same. The effectiveness is dependent on the nature of the particle, the thickness of the tissue or organ, and the characteristics of the material or organ to which such a dose is administered. Thus, to account for such differences in effectiveness, another term, called dose equivalent, is used. The SI unit of dose equivalent is Sievert, which is numerically equivalent to Gy multiplied by the appropriate weighting factor corresponding to biological tissue or organ. For example, the weighting factor (W_R) for many tissues is 0.3, whereas it is 0.03 for bone surfaces. The radiation weighting factor is also dependent on the energy of the particles. For example, for neutrons with less than 10 keV, $W_R = 5$, whereas it is equal to 20 for neutrons greater than 100 keV.

For purposes of administered dose of a radiopharmaceutical, the package insert contains a table that lists dosage for the "average" patient as a function of administered activity. This information may be used for calculation of radiation dose. If needed, a medical physicist will calculate administered dose based on Medical Internal Radiation Dose (MIRD) committee recommendations.

External exposure to ionizing radiation as a result of occupation is measured using dosimeters. Three different types of dose monitors are commercially available. They are pocket dosimeters, film badges, and thermoluminescent detectors (TLDs). Pocket dosimeters are GM counting-based digital dosimeters, which provide immediate reading. Film badges are the least expensive and most popular. Using appropriate filters in the film holder, accurate readings to exposure to different particles can be measured. The major disadvantage with film badges is the waiting period required for developing and processing films. In TLDs, the radiation received is stored in holders containing crystals of LiF or manganese-activated calcium fluoride. Subsequently, during measurement, the crystals are heated to required temperatures such that they emit light. When measured, the emitted light provides a measure of absorbed dose.

REGULATORY REQUIREMENTS

The regulations of various advisory groups and government organizations have to be met in handling, use, and disposal of radioactive material and radiopharmaceuticals. These include the FDA, NRC, Department of Transpor-

tation (DOT), Environmental Protection Agency (EPA), and Occupational Safety and Health Administration (OSHA). Of these, the FDA regulates safety, stability, efficacy, and toxicity of the radiopharmaceuticals; NRC regulates all reactor-produced by-products regarding use, handling, disposal, and radiation safety and protection of workers and the public using the facilities. Title 10 of the Code of Federal Regulations, 10 CFR 20, contains the regulations for radiation protection, whereas 10 CFR 35 addresses medical uses of radioactive materials. Title 49, 49 CFR, addresses packaging and transportation of radioactive materials. In addition, all USP requirements have to be met for a radiopharmaceutical. The International Committee on Radiation Protection (ICRP) and the National Committee on Radiation Protection (NCRP) provide radiation dose recommendations for adoption to other regulatory agencies. The NRC requires that licensees follow the ALARA philosophy regarding radiation exposure. ALARA is an acronym for as low as reasonably achievable. Under the ALARA concept, when radiation exposure of a worker exceeds 10% of the allowed occupational limit, an investigation is required. If it exceeds 30%, investigation and corrective action are necessary per NRC requirements.

As with any other pharmaceutical, radiotracers used as pharmaceuticals are subject to all regulatory requirements. The radiopharmaceutical manufacturer must, at a minimum, satisfy the requirements of the NRC and the FDA.

RADIOLABELING OF PHARMACEUTICAL AEROSOLS AND γ -SCINTIGRAPHIC IMAGING FOR LUNG DEPOSITION

Hak-Kim Chan

University of Sydney, Sydney, New South Wales, Australia

OVERVIEW

Inhalation aerosols have been used successfully to deliver drugs to the lung for local and systemic therapeutic effects. In vivo evaluation of pharmaceutical inhalation products is achieved by γ -Scintigraphic imaging of the aerosol deposited in the lung. Imaging provides direct information on the amount and location of the drug deposited in the lung after inhalation (1). This local bioavailability, rather than the systemic bioavailability after absorption, is pertinent to drugs that act directly on the lung. For drugs that act systemically, deposition site will affect the rate and extent of absorption in the lung. As a result, lung deposition using γ -Scintigraphy has been proposed for bioequivalence studies of aerosol products (2). The deposition data can be linked further to the clinical response and in vitro particle size distribution, adding a new dimension to the inter-relationship between them.

To measure lung deposition by imaging, the aerosol must be first labeled or tagged with a suitable radionuclide. Radiolabeling techniques have been developed for current inhalation products including nebulizers, propellant-driven metered-dose inhalers (MDIs), and dry powder inhalers (DPIs).

Lung imaging is achieved using a γ -Camera. The camera creates an image of the γ -Rays emitted by the radionuclide in the lung (3). In the past, numerous lung deposition studies on radiolabeled aerosol products have been carried out using planar imaging by which only the anterior or posterior 2-Dimensional view of the lung is collected. However, because the lung is a 3-Dimensional object, spatial distribution of the aerosol in the lung can be best obtained using tomographic (rather than planar) imaging such as single photon emission computed tomography (SPECT). SPECT is a technique for producing cross-sectional images of radionuclide distribution in the body. This is achieved by imaging the lung at different angles (e.g., 64 or 128 images/180° or 360°) around the thorax using a rotating γ -Camera, followed by computational image reconstruction.

BACKGROUND OF RADIOLABELING PHARMACEUTICAL AEROSOLS

It is a prerequisite that the pharmaceutical aerosols can be suitably radiolabeled before any lung scintigraphic imaging can begin. Ideally, the drug can be directly radiolabeled, i.e., chemically by substitution of an atom in the drug molecule with a radioactive isotope. This can be achieved using positron emitters, e.g., C-11, N-13, and O-15 atoms. Positrons are positively charged electrons that when combined with an electron, produce two γ -Rays with equal energy (511 keV) emitted at 180° to each other. Theoretically, because C, N, and O atoms are present in all organic molecules, they can be used to label virtually any drug. In reality, the use of these atoms is limited by their short half-lives (e.g., 20, 10, and 2 min for C-11, N-13, and O-15 atoms, respectively), relative to the time taken for manipulating the drug (including organic synthesis for radiolabeling and successive processing for product characteristic assurance such as particle size distribution of the aerosol particles). Further, to produce these positron emitters, it is necessary to have a nearby cyclotron facility, which means extra cost. So far, only three antiasthmatic compounds have been successfully radiolabeled by positron emitters: ipratropium bromide (Br-77) (4), triamcinolone acetonide (C-11), and fluticasone propionate (F-18) (5). This is indicative of the difficulties for direct radiolabeling.

Because of the forementioned limitation, γ -Emitters have been used to radiolabel the drug indirectly for γ -Scintigraphy. In this case, the radiolabel associates with the drug by physical means instead of by chemically incorporating into the drug molecule via covalent bonds. Thus, instead of being a direct chemical approach, it is an indirect radiolabeling. Technetium-99m is the most commonly used pure γ -Emitter for indirect radiolabeling of pharmaceutical aerosols. The γ -Ray of ^{99m}Tc has sufficient energy (140 keV) to penetrate body tissues without significant absorption or scattering, but when it reaches the detector of the γ -Camera, it will be absorbed and converted into light photons, thus optimal for

γ -Camera imaging. The half-life of ^{99m}Tc is 6 h, which is long enough for handling and imaging but not too long as to increase the radiation dose to the subject unnecessarily. As a result, ^{99m}Tc is used for the majority of nuclear medicine imaging studies. Once inhaled into the lung, ^{99m}Tc can have a much shorter biological half-life depending on the physical form, e.g., as diethylenetriamine penta-acetic acid (DTPA) or DTPA complex, it will be absorbed rapidly from the lung into systemic circulation, followed by glomerular filtration in the kidney to the bladder where it is excreted in the urine. The whole process could take less than 2 h if the subject drinks plenty of water.

Regardless of the type of aerosol products to be radiolabeled, a fundamental requirement in the radiolabeling of aerosol products is that the radiolabel must associate with the drug such that not only the radiolabel distribution matches the drug distribution but also that the radiolabel distribution matches that of the unlabeled commercial product.

RADIOLABELING OF NEBULIZER SOLUTIONS

Radiolabeling of nebulizer solutions is by far the simplest among the aerosol products and is achieved by simply mixing the radionuclide with the drug solution. Because the radionuclide and the drug are uniformly distributed in the solution and provided that there is no precipitation of the ingredients occurred, each nebulized aerosol droplet would contain both radioactivity and drug in proportion to the droplet size. ^{99m}Tc in complexing with DTPA or human serum albumin is widely used as the radionuclide. Sodium pertechnetate is not suitable because the free anion, as with iodide, has a high affinity for the thyroid. Lung deposition of nebulized salines and drug solutions, including nedocromil sodium (6), salbutamol, fenoterol, ipratropium bromide, carbenicillin, pentamidine isethionate (7), flunisolide (8), and liposomes containing beclomethasone dipropionate (9), has been studied using this radiolabeling technique of mixing the radionuclide with the drug solution.

RADIOLABELING OF PROPELLANT-DRIVEN MDIs

Historically, there are three major approaches of radiolabeling suspension MDIs, developed by Few et al. (10), Newman et al. (11), and Kohler et al. (12). The first two methods were initially developed for polymeric

Scheme 1 MDI radiolabeling (10)

Elution of ^{99m}Tc as sodium pertechnetate from a ^{99}Mo - ^{99m}Tc generator
 Adjustment of pH to 7–9 with concentrated NH_4OH
 Addition of a drop of 5% tetraphenylarsonium (TPA) chloride aqueous solution
 Extraction of ^{99m}Tc -TPA into chloroform^a
 Separation by passing through phase-separation paper^b
 Collection of the filtrate (the CHCl_3 phase containing the ^{99m}Tc -TPA)
 Evaporation of the CHCl_3 to dryness
 Reconstitution in the appropriate medium containing the compound for radiolabeling

^aFor example, by mechanical shaking or sonication the solution with CHCl_3 .

^bFor example, Whatman 1^P silicone-treated phase-separation filter paper.

particles but were later modified for the radiolabeling of drugs.

Early in 1970, Few et al. (10) radiolabeled polystyrene particles for a mucociliary clearance study. The radiolabeled aerosols were produced by a spinning disk generator. The radiolabeling technique involves the key steps of extracting sodium pertechnetate ($\text{Na}^{99m}\text{TcO}_4$) into chloroform as tetraphenylarsonium pertechnetate followed by evaporation of the chloroform. A solution of polystyrene is then added to the radioactive residue and dispersed (Scheme 1). This technique has subsequently been adopted by other workers for radiolabeling pharmaceutical MDIs of sodium cromoglycate (13, 14). It is important to note that in this technique, the complexing agent tetraphenylarsonium chloride is classified as poisonous (15). Although the actual amount of the compound inhaled is in the nanogram range, safety to the researchers and the subjects inhaling the aerosols has to be carefully ensured.

Another way to radiolabel the pharmaceutical MDI is to use Teflon particles with a size distribution similar to that of the drug of interest (Scheme 2). This was carried out in 1981 by Newman et al. (11) who used Teflon particles of mean size $2 \pm 0.4 \mu\text{m}$ to mimic the MDI aerosols of bronchodilators. Thus, the Teflon particles were used as a surrogate for the drug. The Teflon particles were almost monodispersed and were produced using a spinning disk aerosol generator. However, this approach is limited by the physicochemical characteristics of the Teflon particles being different from those of the drug particles. Also, the aerosol particle size distribution of the Teflon may not match that of the drug. By co-administering a physical mixture of the radiolabeled Teflon particles with the drug

Scheme 2 MDI radiolabeling (11)

Elution of ^{99m}Tc as sodium pertechnetate from a ^{99}Mo - ^{99m}Tc generator
 Removal of sodium by passing the eluate through a cation exchange column
 Collection of the filtrate
 Evaporation of the filtrate to dryness
 Addition of Teflon particles suspended in 40% alcohol
 Generation of radiolabeled Teflon particles by spinning disc technique^a
 Collection of radiolabeled Teflon particles
 Transfer of the radiolabeled particles to an empty canister
 Addition of the content from a commercial MDI^b into the canister^c containing the radiolabeled particles, followed by recrimping of the MDI
 Mixing by sonication

^aFor example, a spinning speed of 62,000 RPM had been used.

^bFor example, the MDI is chilled at -60°C before the transfer is carried out.

^cFor example, the canister is chilled at -60°C before the transfer is carried out.

salbutamol, the lung deposition and clinical response have been monitored simultaneously (16, 17).

The first attempt to radiolabel drug particles (instead of polymers such as polystyrene or Teflon particles) for pharmaceutical aerosols was carried out on fenoterol and salbutamol by Kohler et al. (12) (Scheme 3). However, it was later found that the method would change the particle

Scheme 3 MDI radiolabeling

Elution of ^{99m}Tc as sodium pertechnetate from a ^{99}Mo - ^{99m}Tc generator
 Extraction of ^{99m}Tc -TPA into methyl ethyl ketone (MEK).^a
 Repeat the extraction if necessary.
 Separation of the aqueous and MEK phases^b
 Collection of the MEK phase (containing the pertechnetate)
 Evaporation of the MEK to dryness in a glass beaker
 Addition of propellant^c and surfactant^d to the dry pertechnetate
 Concentration by evaporating the propellant to 0.2 mL
 Transfer of the propellant containing the pertechnetate and surfactant into an MDI canister to be radiolabelled, followed by recrimping of the MDI
 Mixing by shaking

^aFor example, by shaking the pertechnetate solution with approximately equal volume of MEK.

^bFor example, in a separating funnel.

^cFor example, Freon 11, 5–10 ml had been used.

^dFor example, 1% sorbitan trioleate had been used.

(From Ref. 12.)

Scheme 4 MDI radiolabeling

First 4 steps are the same as in Scheme 3.

Evaporation of the MEK (containing the pertechnetate) to dryness in an empty canister

Transfer of the content from a commercial MDI into the canister containing the pertechnetate for radiolabeling, followed by recrimping of the MDI

Mixing by sonication

This method is simpler than Scheme 3 as it does not involve the propellant concentration step and the subsequent transfer of the concentrate. (From Ref. 18)

size distribution of the labeled aerosol, resulting in a coarser aerosol than the unlabeled product. The method, after subsequent improvement by Summers et al. (18) (Scheme 4), has become widely used for the radiolabeling of MDIs. This method is preferred over other methods because it does not involve extraction with tetraphenylarsonium chloride and chloroform.

It is worth noting that each of the radiolabeling examples noted previously can be further modified for the study need. For example, the drug particles can be suspended in the organic phase containing the radiolabel and spray-dried, followed by reconstitution in the propellants, as carried out on salbutamol sulfate (19).

Although the radiolabeling methods have been widely used, the mechanism of association between the radiolabel and the drug particles has been studied only recently. The study by Farr (20) on the MDI systems indicated that in the CFC formulation, the radiolabel $^{99m}\text{TcO}_4^-$, being hydrophilic, would associate with hydrophilic domains including the surface of hydrophilic drug particles and the interior of surfactant reverse micelles. There is a need to extend the study to other systems on hydrophobic drugs and on non-CFC propellants. See Table 1 for methods of radiolabeling MDIs.

RADIOLABELING OF DPIs

A method of wide application to radiolabeling of dry powders is by adsorbing the radiolabel on the particles in a suitable liquid (Scheme 5). This is achieved by wetting the drug particles with a nonsolvent containing the radiolabel, followed by evaporation of the solvent, leaving the radiolabel on the surface of the drug particles. The method has been applied to radiolabel terbutaline sulfate and budesonide (32, 33). Factors affecting the radiolabeling of dry powder formulations include the physicochemical nature of the drug, choice of nonsolvent

Table 1 Examples of radiolabeling pharmaceutical MDIs

^cFreeze drying has been used for water removal.

^dBlend with lactose carrier, if required.

for the drug, solubility of radiolabel in the nonsolvent, moisture level, electrostatic charge, and the number of processing steps (30). Unfortunately, the details still generally remain as proprietary information and are not available in the literature. For example, exactly how the spherical agglomerates of budesonide powder are to be wetted with the ^{99m}Tc solution to ensure reproducible radiolabeling has not been reported.

Alternatively, a method resembling Scheme 1 can be used, provided the drug to be radiolabeled will not dissolve in CHCl₃. This method involves the same first six steps as in Scheme 1. After the filtrate (the CHCl₃ phase containing the ^{99m}Tc-TPA) is collected, it is added to the drug powder. The CHCl₃ is then evaporated, e.g., at 70°C, leaving the radiolabel with the powder. The powder is ready for filling into the DPI. Bronchodilators (salbutamol, terbutaline sulfate) and prophylactics (nedocromil sodium)

for asthma have been successfully labeled using this technique for lung deposition studies (31, 34). There was also an earlier method for the radiolabeling of dry powders (primarily sodium cromoglycate) by spray-drying (35, 36). The basic principle can be considered the same as that in Scheme 1 for MDI in that radiolabeled particles were produced by evaporation of radiolabel-containing atomized droplets. The method is very straightforward (Scheme 6) but suffers the limitation that spray-dried particles may not be physicochemically the same as those in the commercial products. This is because milling rather than spray-drying is normally used for micronization of the drug particles. Spray-drying, following ^{99m}Tc adsorption to the surface of the particles, has also been used to prepare radiolabeled cromoglycic acid and nedrocromil powders (37). The exact mechanism of association between the radiolabel and the drug particles is unknown and is generally regarded as a surface-coating phenomenon. However, the surface is proportional to the square of the particle size, whereas the volume (drug mass) the cube of the particle size. It follows that to have a match between

the radiolabel and drug mass in the aerosol, the radiolabeled particles must exist as agglomerates rather than as single particles. See Table 2 for examples of radiolabeling DPIs.

γ-SCINTIGRAPHIC IMAGING FOR LUNG DEPOSITION

Aerosol deposition in the lung is measured by γ-Scintigraphy routinely used in nuclear medicine. A γ-Camera consists of a collimator located in front of a detector, behind which is an array of photomultiplier tubes (3). The collimator allows only γ-Rays with a defined angle to reach the detector. The detector, which is a scintillation crystal made of sodium iodide, converts the γ-Rays to light photons. The photomultiplier tubes then transform the light photons into an electrical signal that can be displayed in the X- and Y-position on a monitor such as a cathode-ray tube or a computer. Planar imaging, which provides 2-Dimensional anterior and/or posterior views of the lung, has been commonly used in the past to study deposition. This involves inhalation of the radiolabeled aerosols with a collimated γ-Camera placed in front of or behind the chest of the subject. The image is formed as the γ-Ray photons emitted from the radiolabeled aerosol in the lung fall on the camera detector. The primary advantage of planar imaging is that the image acquisition and data processing are less effort-demanding. Also, compared with tomographic imaging (see SPECT, below), it can utilize a lower radioactivity dose. However, a severe limitation of planar imaging is that it compresses the 3-Dimensional lung into a 2-Dimensional view, and thus it cannot provide 3-Dimensional spatial information about the aerosol distribution in the lung. This may become more critical if

Fig. 1 Fast 1-min SPECT coronal section lung images of a healthy subject after inhalation of normal saline aerosols containing ^{99m}Tc -DTPA in large and small droplets (7 μm , top 3 μm , bottom) generated by air-jet nebulizers. The difference in deposition between the two aerosols is clearly shown in these images.

thelung deposition data are to be used for bioequivalence comparison (1,2).

Three-dimensional image data can be achieved by SPECT. SPECT has been used to measure lung deposition of aerosols in a number of studies (6, 39–44, 49). This involves imaging the lung at different angles using a SPECT camera rotating round the chest of the subject after radioaerosol inhalation. The acquired raw data are then processed by high-speed computers to reconstruct the lung images in the coronal, sagittal, or transverse section (e.g., see Fig. 1 for the coronal section images). The question remains as to whether SPECT offers any advantage over planar γ -Scintigraphy for quantitation of total (as opposed to regional) lung deposition. This can be answered by comparing the measurement of a known amount of radioactivity in a lung phantom (e.g., a perspex container with size and shape similar to the human lung) using both techniques. The results of this comparison are not yet published.

Misconceptions of SPECT

High-dose radiation has often been quoted as a disadvantage of SPECT (1). Obviously, the radioactive dose should never be administered more than required, regardless of whether SPECT or planar imaging is used. It is interesting to note that a number of planar imaging studies were carried out in the past using radiation doses comparable with those for SPECT (43). In practice, the dose consideration must be balanced by the benefits of the deposition details gained using SPECT. If planar imaging cannot provide the required deposition details, then SPECT should be considered. Otherwise, carrying out a suboptimal study using planar imaging without obtaining the deposition data required is not justified because it exposes the subjects to unwanted radiation exposure. The amount of radioactivity delivered to the lung for SPECT is approximately 60 MBq, which is equivalent to an effective whole-body dose of 0.4 mSv. In comparison, the

Fig. 2 Lung images of a healthy subject after inhalation of an aqueous aerosol containing ^{99m}Tc -DTPA generated by a novel aerosol inhaler, the AERx system of Aradigm Inc. (Ref. 42). *Left*: planar images from aerosols inhaled using two different breathing maneuvers [vital capacity (VC) or fixed volume (FV) of 1 L above the functional residual capacity] and two different postures as stated. *Right*: a midcoronal image acquired using SPECT. Superposition of the lung outline from the transmission SPECT image (right) on the emission SPECT image confirmed the excellent peripheral deposition of the aerosol.

average radiation dose from background radiation is approximately 2–3 mSv in a year, depending on the geographic location.

Another common misconception about SPECT is the long image-acquisition time and the associated problem of relocation of deposited aerosol particles in the lung (1). Historically, this was true when a single-head SPECT γ -Camera was used in the 1980s for lung deposition because the imaging process took approximately 15–20 min (43). During this length of time, relocation of the radiolabel occurred as confirmed by comparing lung images immediately before and after the SPECT acquisition. Radiolabel movement would create problems of inconsistent projection during image reconstruction, leading to artifacts in the reconstructed images. Despite these limitations, SPECT has been shown to be superior to planar imaging in differentiating lung deposition among aerosols (39). In a more recent study on a novel inhaler using different breathing maneuvers (42), SPECT was able to detect a subtle difference in the aerosol deposition that was not observed using planar imaging (Fig. 2). The problem of long acquisition time has recently been resolved by fast dynamic SPECT (44, 49). Using a triple-head

γ -Camera, the SPECT acquisition time has been reduced to only 1 min (Fig. 1). Thus, 20–30 complete individual 1-min SPECT image acquisitions can be collected in 20–30 min, making dynamic study feasible. The technique can also be applied to study clearance of an aerosol from the lung after deposition (Fig. 3).

Attenuation and Scatter Correction

Attenuation occurs when the γ -Ray photons emitted from the radionuclide in the lung are absorbed by the body tissues before reaching the camera detector. Attenuation causes a reduction in measured radioactivity counts. Because of the heterogeneous nature of the thorax tissues (lung, muscles, bones), the attenuation cannot be assumed to be uniform and must be measured. Experimentally, the attenuation information can be obtained from a

Fig. 3 The time course of activity clearance from the lung measured by fast 1-min SPECT on a healthy subject after inhalation of normal saline aerosols containing ^{99m}Tc -DTPA in large and small droplets (7 μm , \blacklozenge ; 3 μm , \blacksquare). In the plot, 2-min frames are used for clearer illustration.

transmission scan that uses an external γ -Radiation source for imaging of the thorax. To avoid uncertainty in image re-alignment between studies, transmission imaging is best carried out simultaneously with the aerosol (emission) study (45). This can be achieved by attaching the radiation source to the γ -Camera during the aerosol lung image acquisition. The use of the same radionuclide for the transmission as the emission imaging would eliminate uncertainties attributable to differences in the photon energy. When simultaneous emission–transmission imaging is not feasible, the attenuation information can also be obtained from a separate transmission study before the aerosol inhalation. Alternatively, x-ray computerized tomography (CT) scanning can be carried out, but it involves a higher radiation dose to the subject. Also, the separate transmission scan would require extra time, and image re-alignment may be more difficult.

Scatter occurs when the γ -Ray photons emitted from the radionuclide in the lung encounter the thorax tissues and change the traveling direction from their original path. Therefore, scatter causes mispositioning of the detected counts, leading to a loss of image contrast and quantitative accuracy. Quantitative assessment of aerosol deposition would require both attenuation and scatter correction. The latter is also important for proper image reconstruction in SPECT. For additional reading, texts of SPECT imaging are recommended (46, 47).

Data Analysis

Image processing

Planar images can be analyzed on the anterior or posterior view. Because the lung has a thickness, the radiolabel may occur anywhere along the thickness. The effect owing to deposition at varying thicknesses can be minimized by taking the geometric mean of the anterior and posterior images.

Compared with planar images, SPECT data require more rigorous treatment involving mathematical image reconstruction algorithms. Because of simplicity and speed, the filtered back-projection algorithm has been used in clinical SPECT studies including aerosol deposition in the lung. Filtered back-projection uses summation techniques using projections (count rate profiles) of the acquired image data. Artifacts in the back-projected image are corrected by filtering (using mathematical operations) the data before or after reconstruction. Because of the nonuniform attenuation regions of the thorax, other iterative reconstruction techniques involving attenuation and scatter correction have also been used (46, 47).

Drawing of the lung region

The lung outline is obtained from the transmission image or from ventilation image using radioactive gases such as $^{81\text{m}}\text{Kr}$, when available. After superimposing the lung outline on the aerosol emission image, the lung is then divided into different regions of interest, and the amount of activity in each region is measured. Regions such as apex and basal or central and middle and peripheral are most commonly used. A conventional way to analyze aerosol distribution (or deposition pattern) is to express it as the ratio of the activity in one region to another, e.g., peripheral to central, which is conventionally defined as the penetration index. However, there is no consensus on how the size and shape of each region should be drawn. For example, both rectangular regions and lung shape regions have been used for the planar images in the past, but the regions can vary from laboratory to laboratory. Thus, there is a need to standardize the methods for drawing lung regions for comparing studies among different laboratories. The rationale of drawing the lung regions is that the peripheral region should contain more small airways than the central region. In a planar image, there will inevitably be extensive overlapping of structures in the lung. In relative measurement or comparative studies using the same subject as his or her own control, the region size and shape may not be as crucial as in the absolute measurement when the aim is to assign the deposition to certain anatomical structures. The latter is a formidable task because the whole lung contains approximately 1.6 million airway branches. It has recently been attempted on SPECT images with the aid of computer modeling (48). Success will provide valuable information for interpreting the γ -Camera images in relation to the aerosol distribution in the airways.

CONCLUDING REMARKS

Radiolabeling of nebulizer solutions, propellant-driven MDIs, and DPIs is generally well documented. For some DPIs, the procedure may still be lacking in sufficient detail to ensure reproducible radiolabeling. Deposition of radiolabeled aerosols in the lung has been measured primarily by planar imaging. Tomographic imaging using SPECT can provide 3-Dimensional information about the spatial distribution of the aerosol in the lung. The recent development of fast dynamic SPECT has made it the method of choice for aerosol imaging in the new millennium.

ACKNOWLEDGMENTS

I am grateful to Karen Smith for technical assistance and to Stefan Eberl for the availability of Figs. 1, 2 and 3.

William J. Thomsen

Arena Pharmaceuticals, San Diego, California, U.S.A.

INTRODUCTION

A paradigm shift has occurred in receptor-based drug discovery based upon the elucidation of the complete human genome and advances in genomics research, which have revealed a plethora of potential new receptors on which to focus drug discovery efforts. Based on sequence, structural, and functional similarities of a great number of receptors, these receptor targets can be grouped into relatively few multigene superfamilies. Molecular biological approaches have also revealed that additional receptor subtypes and isoforms are generated through multiple mechanisms. The current challenge lies in the development and application of new strategies for rapidly mining the receptor genome sequences to establishing and understanding their function, which has been referred to as “functional genomics.” Practical problems and approaches to assays for the characterization of the ligand binding and elucidating signaling properties of expressed orphan receptors are critically evaluated. The ensuing characterization of orphan receptors is expected to reveal therapeutically important receptor targets that will serve as a platform for much of the drug discovery enterprise. These findings will spur the discovery and development of a new generation of receptor-subtype specific drugs with enhanced therapeutic specificity.

CONCEPT AND DEFINITION OF RECEPTORS

To paraphrase Voltaire, if receptors did not exist it would be necessary for pharmacologists to invent them. In fact, this is precisely what J.N. Langley did around the turn of the century when he suggested the existence of “receptive substances” through which tissues were able to selectively recognize agonist and antagonist chemicals (i.e., ligands) and, importantly, also provide a mechanism for the translation of this recognition event into a physiological response. Thus, a basic and enduring operational definition of a receptor is that it “must recognize a distinct chemical

entity and translate information from that entity into a form that the cell can read to alter its state accordingly, for example, by a change in membrane permeability, activation of a guanine nucleotide regulatory protein, or an alteration in the transcription of DNA” (1). Hence, the attributes of *ligand recognition* and *signal transduction* are both fundamentally necessary to define receptors. The transduction process may be mediated through an integral part of the receptor structure and may involve receptor interactions with additional nonreceptor proteins. A signal transduction feature of many ligand–receptor interactions is the activation of a kinase domain that initiates phosphorylation in a signal transduction pathway.

This definition has been the basis for an enormous body of scientific investigation into the function and regulation of receptors and mechanisms of drug action. However, final proof of the existence of receptors did not occur until relatively recent applications of modern biochemistry and molecular biology to purify, sequence, clone, and express pure receptor proteins. This lack of proof notwithstanding, the therapeutic basis of many modern, and not so modern, drugs resides in their specific interactions with receptor molecules located in the plasma membrane or cytosol of target cells. In fact, these specific interactions have provided the experimental basis for their discovery and development.

CRITERIA FOR RECEPTOR CLASSIFICATION

Primacy of Molecular Structure

Historically, pharmacologists classified receptors based on the concept that a single receptor mediated a pharmacological response to a single endogenous agonist and that receptor subtypes could be defined primarily by pharmacological properties. Receptor subclassification systems were dependent upon the availability of selective and potent natural substances (toxins and alkaloids) or synthetic ligands, which could selectively elicit or inhibit biochemical and physiological responses from receptors. In some

cases, subtypes could be distinguished by different signal transduction mechanisms associated with each receptor subtype. While this approach led to understanding the molecular and cellular mechanisms of many drugs and to significant therapeutic advances, it did not provide evidence of the numerous and diverse subtypes that are now known to comprise all receptor families.

The enormous molecular diversity and multiplicity of receptor subtypes for a given neurotransmitter or hormone were not fully appreciated until the application of modern molecular biology techniques. The GPCRs (G-protein coupled receptor) currently comprise the single largest receptor superfamily, with estimates of over 1000 receptors in the human genome. Within each receptor family, the multiplicity of receptor subtypes has greatly exceeded the numbers that were predicted on the basis of pharmacological data alone. Now frequent cloning of many receptor genes and the study of the encoded recombinant proteins have both revolutionized the criteria necessary for classification of receptors, which otherwise could not be distinguished pharmacologically and provided fundamental insight into mechanisms of drug action at the molecular level.

Current classification criteria for receptors developed by the Committee for Receptor Nomenclature and Drug Classification of the International Union of Pharmacology (NC-IUPHAR) are based on a combination of information derived from molecular structure (structural), pharmacological characteristics of the receptor (operational or recognitory) and on signal transduction mechanisms used by the receptor (transductional) (1). Of these three essential criteria, the amino acid sequence of the receptor provides a definitive identification of a distinct protein and thus serves as an unambiguous primary basis for classification. Identification of the endogenous ligand or ligands provides a secondary means to group receptors into families. Integration of pharmacological evidence obtained from radioligand binding studies of selective agonists, antagonists, and allosterics (modulatory ligands), and their characterization in functional assays (changes in intracellular cAMP levels, calcium, or reporter gene assays) enables a comprehensive assessment for classification based upon all three essential criteria.

Receptors can be most reliably subclassified and defined on the basis of antagonist affinities, whereas data obtained with agonists are considered much less useful since intrinsic activity and potency have been found to be cell and tissue dependent. Information on receptor-effector mechanisms that reflect the molecular signaling properties of the receptor provides another tier for receptor classification, although transduction mechanisms for novel receptors may be unclear and subject to controversy.

Furthermore, the use of heterologous cellular expression systems for the study of recombinant receptors has revealed the potential for receptor subtypes to initiate signaling events not normally associated with their physiological role. These studies have also demonstrated that the ultimate response to receptor activation is cell-type specific. Hence, the potential ambiguity that may arise in defining receptor transductional characteristics has led to the recognition that this characteristic has more limited value among classification criteria. The question of how to integrate receptor structural information, pharmacological characteristics, and transductional properties into a rational scheme of receptor classification and nomenclature is a subject of continuing discussion among pharmacologists (2).

Receptor Superfamilies, Families, and Subtypes

From the vast number of amino acid sequences deduced from fully sequenced genomes and from cloned receptor proteins, primary amino acid and structural similarities have been identified that are common to numerous receptor types that possess distinct pharmacology. Putative receptor genes usually contain recognizable sequence motifs to suggest a superfamily of receptor they might encode. This homology method has been widely used to find common sequence motifs that typically occur in the extracellular ligand binding domains, transmembrane domains, or within intracellular domains of receptors. This has enabled receptor classification into superfamilies based on sequence similarities that encompass many receptor proteins that differ pharmacologically but are structurally and functionally similar since they share a single molecular signal transductional mechanism. The "common structure–common function" concept is not unique to receptors but originates from the observation that families of proteins are derived from a common ancestral gene. Receptor subtypes within a superfamily are generally considered to have arisen through evolutionary mechanisms of gene duplication and genetic drift leading to divergence from a common progenitor receptor gene rather than reconstruction of new genes *de novo*. Indeed, members of a family are often clustered in a relatively small region of the human chromosome, and the genomic organization of highly homologous receptors (and receptor subunits) often reveals identical structures consisting of the same number of protein-encoding exons. For many members of the GPCRs superfamily, the entire protein is encoded by only a single exon.

Despite the enormous multiplicity of receptor subtypes, a limited number of basic superfamilies have been recognized that currently suffice to accommodate all of the signal transducing receptors. As an example, in the GPCRs

human somatostatin receptors are shown, using the single-letter amino acid code. The seven transmembrane regions are indicated, which show the highest level of sequence identity from the overall receptor sequences. Biophysical and biochemical studies have shown that these sequences

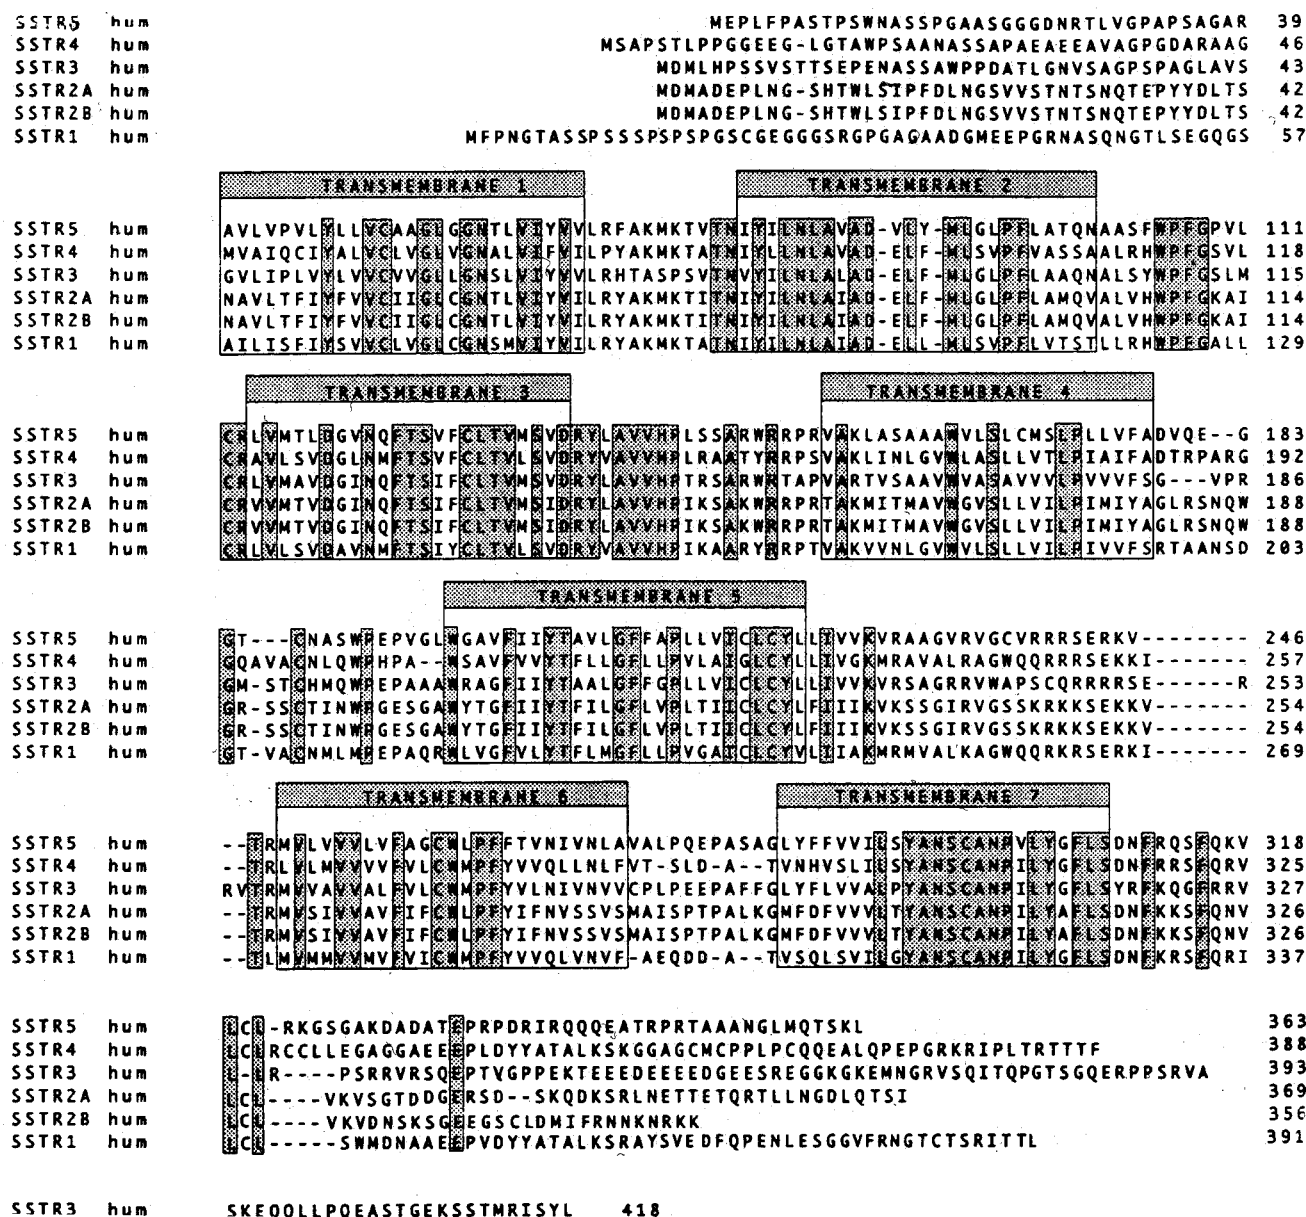

Fig. 1 Primary amino acid sequence comparison between five members of the human somatostatin receptor family. The amino acid sequences are aligned, using the single-letter amino acid code. Gaps introduced in the sequences to optimize the alignments are represented with dashes (–). The boxes indicate amino acids that are identical in all five receptor subtypes. The highest level of homology occurs within the seven canonical transmembrane domains of the human SST receptors (indicated above the sequences) and these domains have been derived by a combination of hydropathy analysis and comparison with the transmembrane domains of the other G-protein coupled receptors. The high level of homology among the members of the SST receptor family in the seven membrane spanning domains is shared by other G-protein coupled receptors that are coupled to inhibition of adenyllyl cyclase.

form a bundle of transmembrane α -helices in the plasma membrane and that the amino terminus is present on the extracellular surface and the carboxyl terminus is present on the cytoplasmic surface of the membrane. Other smaller structural motifs act as functional microdomains in GPCRs. These domains have been mapped by site-directed and deletion mutagenesis studies, generation of receptor chimeras, and through the use of antibodies and include sequences critical for ligand binding, coupling to G-proteins and phosphorylation (Fig. 2). Functionally, all agonist-activated GPCRs signal through interaction with heterotrimeric G proteins, triggering a diverse array of cellular responses. Other major recognized superfamilies include the ligand gated-ion channel receptor (LGCR), receptor tyrosine kinase (RTK), receptor protein tyrosine phosphatase, tumor-necrosis factor (TNF)/nerve growth factor (NGF) receptor, TGF- β serine/threonine kinase receptor, and nuclear receptor superfamilies. Undoubtedly, as many novel sequences of receptors become known that cannot be accommodated within the existing superfamily framework, and their signal transduction properties are defined, new superfamilies of receptors will be proposed. Receptors are further subclassified into receptor families and subfamily groups on the basis of relative

sequence homologies, operational and signal transduction mechanisms. The nomenclature system frequently employed has been to name families with reference to their endogenous ligands, for example, glutamate, serotonergic (5-HT), dopaminergic, epidermal growth factor. Each family typically consists of multiple receptors subtypes that share similarities in their molecular biological, pharmacological, biochemical, and physiological properties. Within a receptor family, members of one subfamily are more closely structurally homologous to one another (on average between 50 and 80%) than to members of other subfamilies (in the range of 25%). However, the current nomenclature system carries forward several notable idiosyncrasies with regard to ligand-receptor systems in which a single endogenous ligand serves as the neurotransmitter for receptors belonging to two distinct superfamilies. Hence, acetylcholine is the transmitter for muscarinic acetylcholine receptors that are GPCRs with seven transmembrane domains (3) and the unrelated nicotinic acetylcholine receptors that are multi-subunit ligand-gated ion channel receptors (LGCRs) (4). Similarly, several neurotransmitters interact with receptors that belong to these two different superfamilies. Glutamate receptors are divided into metabotropic (GPCRs) and the

GPCR Domains

Fig. 2 Seven transmembrane spanning model of the a typical G-protein coupled receptor showing functional domains. The core of about 175 amino acid residues that forms the transmembrane domains (defined by hydrophobicity analysis) are highly conserved among superfamily members. The extra- and intracellular loop regions and C-terminus are much more divergent, even among closely related receptors. Sites for glycosylation are found on the amino terminus and a palmitoylation of a Cys in the C-terminal domain are shown. Intracellular residues involved in G-protein coupling and interaction with receptor-specific kinases that mediate desensitization occur on the intracellular loops.

ionotropic, which include the NMDA, AMPA, and kainate families (LGCRs). GABA receptors are classified as GABA_B (GPCRs) and GABA_A (LGCRs), and purinergic P2 (P2X and P2Y) receptors also have subtypes in both superfamilies. All serotonergic receptors (5HT₁–5HT₇) belong to the GPCR superfamily with the exception of the 5HT₃ receptor, which is a LGCR 5,6).

Multiligand/Multireceptor Families

It is well recognized that all superfamilies contain examples of receptor subtypes that interact with more than one species of endogenous ligand. Receptor binding and tissue-culture experiments have shown that a structurally related family of ligands may bind and activate a single receptor. The existence of families of endogenous ligands that activate either one or more closely related receptor subtypes presents a significant challenge of “receptor promiscuity” to both receptor classification and drug–receptor design. The newly recognized prevalence of such multi-ligand receptor families present among diverse receptor superfamilies suggests that the classical pharmacological dictum of one ligand per one receptor is no longer tenable.

Within the GPCR superfamily, the individual subtypes of CC-chemokine receptors bind and are activated by multiple CC-chemokine ligands. Determining chemokine structure and function is extremely difficult especially when cells contain an ensemble of receptors on their membrane. For example, most chemokine receptors have more than one high-affinity endogenous agonist, and most chemokines bind to more than one receptor subtype. Within the 11 member CC-chemokine receptor family, there are at least five subtypes of chemokine receptors involved in binding the CC-chemokines (also known as β -chemokines): MCP-1, MIP-1 α , and RANTES. Based on studies to date, one receptor (CCR-1) binds all three ligands, another (CCR2) binds only MCP-1, and RANTES binds to CCR1, CCR3, and CCR5. Similar observations of complex ligand–receptor promiscuity are seen with the CXC- or α -chemokine family and five receptor subtypes. Two closely related neutrophil-derived CXC (IL-8) receptors, CXCR-1(IL8R_A) and CXCR-2 (IL8_B), have been cloned whose binding characteristics account for the binding observed with neutrophils. CXCR-1 receptors interact with three ligands (IL-8, GCP-2, and NAP-2) that are also known to bind CXCR-2 receptors.

A second example of multiligand/multireceptor interactions is illustrated by the bone morphogenetic proteins (BMPs), which are members of the TGF- β superfamily. The BMP family of protein ligands has diverse functional roles, including bone and cartilage formation, cell proliferation,

apoptosis, differentiation, and morphogenesis. A number of BMPs have been discovered and, based upon sequence homology, most of the GDFs (growth/differentiation factors) have been added to the BMP family, bringing the number of ligands in this family to around 25. TGF- β , BMP-2, and BMP-7 interact with at least six receptor subtypes of the potentially multimeric Type I and Type II receptors in the TGF- β receptor serine/threonine kinase superfamily. The complexities in devising a uniform, rational nomenclature scheme that incorporates endogenous multiligand-/multireceptor interactions and also is consistent with instances in which a cell surface receptor can simultaneously function as both a ligand for a receptor on another cell and as an independent receptor entity are substantial.

Receptor Subtypes Composed of Combinatorial Subunits

The central tenet of the current classification system is to define a unique receptor subtype for each receptor that is composed of only single polypeptide encoded by distinct gene. As an example, the dopamine receptor family is known to contain at least five distinct subtypes, dopamine D₁–D₅ receptors, each receptor consisting of one subunit encoded by separate genes. A more complex system arises in the case of multisubunit oligomeric receptors, as in the case of the LGCR superfamily. These multisubunit receptors are known to exist as hetero-oligomers with many subunit combinations that comprise distinct subtypes. For several families, homologous genes encoding highly related receptor subunits have been designated by a combination of greek letters and numbers. Molecular cloning studies of GABA_A receptors have identified five different subunit types named α , β , γ , δ , and ρ , which share significant amino acid sequence identity with each other (30–40%) and with other members of the ligand-gated ion channel superfamily. Nearly all of these subunits also have a number of different isoforms (α 1–6, β 1–4, γ 1–3, δ , and ρ 1–2) and all sequences within each isoform family are highly homologous (70–80% identity). Individual GABA_A receptor subtypes are thus defined by the distinct combination of subunits and stoichiometry that compose the oligomeric complexes, such as α 2 α 3 β 3 γ 2, α 1 α 3 β 2 γ 2, and α 1 α 3 β 2 γ 2. However, subunits of the NMDA, AMPA, and kainate receptor-ion channel complexes have been classified using an alternate system; NMDA1 and NMDA2A–D, and glu1-7 and ka1-2 . The combinatorial mechanism of receptor assembly has the potential for producing a large number of receptor subtypes and is a common feature of the multigene families that comprise the LGCR superfamily.

Molecular Mechanisms Producing a Diversity of Receptor Isoforms

Additional variation in receptor sequences occurs through naturally arising mutations, naturally occurring allelic variants, RNA splicing, and RNA editing. For example, the human dopamine D₄ receptor subtype contains a direct repeat of a 16 amino acid segment in the putative third intracellular loop of the receptor. Naturally occurring allelic variants of this receptor subtype contain variable numbers of direct repeat units (e.g., 2, 4, 7 repeats; dopamine D_{4.2}, D_{4.4}, D_{4.7}) producing a substantial number of receptor variants in the human with different primary amino acid sequence but as yet indistinguishable receptor binding and signal transduction pharmacology for a wide range of ligands (7). Other subtype variants occur at the level of RNA splicing giving rise to length variants of the receptor subtype. For example, differential splicing results in the long and short isoforms of the dopamine D₂ receptor, D_{2L} (D_{2A}) and D_{2S} (D_{2B}) (7), and produces two proteins differing by 29 amino acids. RNA editing is yet another mechanism producing sequence and functional diversity and has been found to produce seven different edited forms of the kainate GluR6 subunit, all encoded by only one gene. While many receptors are subject to posttranslational modifications, such as phosphorylation, which modulate receptor properties, these differences are not considered to define a receptor subtype.

Species homologs of the same receptor subtype display a high degree of amino acid sequence homology, typically showing 85–95% sequence identity between species. This is a greater sequence similarity than is usually found between distinct receptor subtypes in the same species. The introduction of cloning has enabled identification of species homologs of receptors that otherwise might be defined as distinct receptor subtypes due to their species-specific pharmacology, as was found in the case of the rat 5-HT_{1B} and human 5-HT_{1B} (5HT_{1DB}) receptors (8). Since a change in as little as a single amino acid within the binding site domain can markedly alter ligand affinity, some receptor species homologs exhibit distinctive pharmacology. A notable example is the comparative binding of the nonpeptide antagonist ligands, CP96345 and RP67580, to the human and rat neurokinin NK₁ receptors. While CP96345 binds with nanomolar affinity to the human NK₁ receptor, it exhibits two orders of magnitude lower affinity for the rat receptor, whereas RP67580 shows selectivity for the rat receptor. The magnitude of the selectivity difference is noteworthy given that the rat and human receptors are 95% identical. Construction of single residue substitutions in recombinant NK₁ receptors demonstrated that an exchange of two

residues was sufficient to reverse the species selectivity of the two ligands. Due to the number of cases in which species homologs differ from human receptor pharmacology, the use of cloned human receptors for drug discovery screening programs is increasingly favored.

Orphan Receptors

Putative receptors identified by gene cloning that exhibit homology to known receptors in the existing superfamilies but for which no known ligands have been identified are referred to as *orphan receptors*. Initially, these novel receptors may be classified based upon the level of sequence homology. When the endogenous ligand for an orphan receptor remains unknown, the receptor may be provisionally named based on the binding of a synthetic ligand to the receptor until the endogenous ligand is identified. As the functions of an orphan receptor are uncovered, these novel receptors frequently become targets for the development of new therapeutics.

LIGAND–RECEPTOR INTERACTIONS DEPEND UPON RECEPTOR CONFORMATIONAL STATES

Resting, Activated, and Desensitized Receptor States Differ in Ligand Affinity

One of the major criteria in receptor subtype classification is the pharmacological selectivity profile as defined by ligand affinities (equilibrium dissociation constant, K_d) and activation constants. Since binding data overcome many of the limitations inherent in studies of biological responses, ligand affinities have provided a practical method to define and classify related subtypes. Nevertheless, accurate comparisons of agonist affinities of cloned receptors with binding affinities characteristic of the native cell type or tissue may be difficult to obtain. Agonist affinities determined for recombinant receptors expressed in distinct heterologous cell types have been found to vary substantially and differ from value characteristic of the native cell type (9). These findings underscore the need to compare ligand affinities and function of an expressed recombinant receptor in several host cell lines and for related receptor subtypes to be expressed in a common host cell line in order to allow accurate pharmacological comparisons (10). Receptor classification schemes will need to take into account the host cell environment when evaluating ligand affinity and functional data.

In contrast to traditional receptor theory, it is now evident from molecular pharmacological analysis that

transitions between receptor states can be induced by interaction of a receptor with a full spectrum of ligands that have very different capacities to activate the receptor. Ligand-induced changes in the population distribution of receptor molecules between these states govern the binding and functional properties of the receptor. As discussed in detail ahead, measurements *in vitro* and *in situ* have revealed the importance of temporal responses in characterizing multiphasic ligand–receptor interactions for the ligand-gated ion channel and GPCRs superfamilies.

An agonist, by virtue of the molecular “information” it contains (e.g., size, 3D configuration, charge distribution, hydrogen- or ionic-bonding residues, chirality), selectively binds to a complementary 3D surface or binding site domain formed by amino acid residues of a receptor protein and initiates a cellular response. Drugs classified as full agonists elicit the maximal response while compounds that only elicit a fractional response are referred to as partial agonists. Regardless of whether the agonist is an endogenous physiological ligand, a natural product, or a synthetic compound, agonist binding is coupled to conformational changes in the receptor protein that involve a molecular transition to a common, active receptor state. As an example, binding of either full, strong, or weak partial agonists to the nicotinic acetylcholine receptor induced a transition to an open channel state that is characterized by the same unitary conductance. Although the frequency and duration of the receptor open state differ, this is indicative of a single, active conformation of the receptor. The simplest schemes for receptor activation take into account that occupation of a receptor (R) by an agonist (L) results in a conformational change in the receptor to create an agonist-activated state (LR*), which can bring about an effect or response, and can be represented as:

where L is the agonist, R represents the unoccupied (inactive) receptor, R* is the active state of the receptor, K_d is the dissociation constant for agonist-receptor binding, and E is the constant describing the equilibrium between the LR and the LR* states of the receptor.

Contemporary models of receptor activation attempt to incorporate increasingly detailed knowledge of multiple conformational states, including desensitized receptor states. A fundamental component of these molecular activation schemes for receptors is that receptors exist in a dynamic equilibrium between three states, an inactive (R), an active conformation (R*) and a desensitized state (R'), and that the biological response to a given ligand is governed by its ability to change the equilibrium (or its relative preference for binding) between the three receptor

states. Continued exposure of LGCRs to agonists promotes a multiphasic conversion to desensitized receptor states that develop on time scales ranging from milliseconds to minutes. Generally, GPCR activation is also followed rapidly by a loss of responsiveness, also termed desensitization, which is then followed by a period of recovery or resensitization. These changes in signaling are tightly regulated, primarily via mechanisms that involve rapid GPCR phosphorylation, internalization of receptors that remove them from the cell surface, and either degradation or recycling back to membrane surface (11).

Many receptors that function as ligand-gated ion channels can be described by a two-state cyclic scheme for receptor desensitization (including only one desensitized state), which was initially deduced from extensive studies of the kinetics of nicotinic acetylcholine receptor (AChR) state transitions induced by ligand binding (12). This model was expanded to a general coupled-equilibria model that described the molecular species and influence of agonists and noncompetitive inhibitors (noncompetitive antagonists) on receptor states (13). As shown in Fig. 3, the model incorporated the fact that the AChR contains two interacting agonist binding sites and a topographically distinct binding site for an allosteric, noncompetitive inhibitors.

For many receptors, the agonist binding site of the receptor protein can interconvert between high and low affinity binding states or receptor conformations. Moreover, differences in affinity of the agonists for the same site in different receptor states may be dramatic. In the case of LGCRs, the desensitized states display higher agonist binding affinity and no receptor-mediated ion permeability. It is the preference for ligand binding to the desensitized receptor that is the driving force underlying conversion to the desensitized state. The binding affinity (K_d) of acetylcholine to the muscle subtype of the nicotinic acetylcholine receptor measured at equilibrium is about 10 nM (desensitized state), 4–5 orders of magnitude below the apparent dissociation constant for the permeability response (activatable state) mediated through the same binding site (14).

Multiple agonist-affinity receptor states have also been described for many GPCR receptor families. GPCRs may adopt either a high-affinity or low-affinity state for agonists (K_H and K_L), which may differ by 1000-fold when characterized in native membranes purified from either brain tissue or derived from cell lines. Low-affinity agonist states for receptors, which typically cannot be determined by direct binding of a radiolabeled agonist, have been measured by employing radiolabeled antagonists and examining the pattern of competition over a wide range of agonist concentrations. For recombinant GPCRs, agonist-induced

changes in affinity depend upon efficient coupling of the expressed recombinant receptor to endogenous G-proteins present in the host cell line, and coupling is highly dependent on the combination of receptor and clonal cell line. For example, agonist-stimulated D₃ dopamine receptor-mediated effects were lacking, and an inability to demonstrate significant affinity shifts for agonist ligands was found in the presence of guanine nucleotides in COS or CHO cells (14). However, receptor coupling to inhibition of adenylyl cyclase was readily obtained for closely related subtypes in the D₂ receptor subfamily, recombinant D₂ and D₄ receptors, expressed in a variety of cell lines (CHO-K1, HEK-293, C6-glioma, Ltk⁻) (15,16).

Antagonist Modulation of Receptor Conformational States

According to classical models for drug–receptor interaction, full competitive antagonists and agonists

share the ability to bind to a common site on the receptor molecule but differ in that antagonists are devoid of intrinsic activity. While a competitive antagonist occupies the binding site of the receptor, it does not promote conversion of the receptor to the active conformation. Indeed, at the biochemical level, nicotinic acetylcholine receptor agonists and antagonists that differ in size and structure (acetylcholine, tubocurarine, and snake venom α -toxins) have been mapped to the same molecular site on the receptor α -subunit and their binding is mutually exclusive. However, recent data suggest that no overlap in the binding site for competitive ligands is required if they bind in a mutually exclusive manner to different binding sites that are present only in different receptor conformations. Competitive antagonists may be subclassified into at least two categories: 1) neutral antagonists that do not exhibit a preference for an inactive or active receptor conformation and have no effect on basal receptor

Fig. 3 Structure and ligand binding sites of the muscle subtype of the nicotinic acetylcholine receptor. The structure is derived from electron microscopy of two-dimensional crystals of receptors in *Torpedo* membranes. The five subunits together form a cylindrical shape approximately 120 Å long with a 70 Å diameter, which spans the membrane. The receptor on the right shows a section along the axis of the receptor and the cation conducting pathway in profile. A 60 Å diameter central hydrophilic tube is present on the synaptic side which is the entrance to the transmembrane ion channel which narrows at the level of the membrane. Current resolution of the receptor cannot resolve dimensions of the ion channel within the membrane bilayer which permeability studies have defined as an aqueous pore of about 7 Å diameter. Locations of the ligand binding sites have been mapped within the receptor structure by fluorescence energy transfer techniques. The two agonist binding sites, one on each α -subunit, are 20–30 Å from the membrane surface and the single allosterically-coupled noncompetitive inhibitor site is located in the channel. Positions of two snake venom α -toxin molecules (peptides of 7500 kD, peptide backbone shown) bound to the synaptic surfaces of the α -subunits are shown for the receptor on the left.

activity and 2) negative antagonists, also termed inverse agonists, which exhibit the defining property of inhibiting agonist-independent receptor activity and possess negative intrinsic activity. Furthermore, negative antagonists stabilize a different receptor conformation (state) than neutral antagonists.

For both LGCRs and GPCRs, whose activity is governed by distributions between inactive and active states, negative antagonists promote conversion of the receptor to an inactive conformation and stabilize a conformation of the receptor that is distinct from the unliganded receptor (resting state). For G-protein coupled receptors, studies of receptors expressed at high levels, using the baculovirus expression system in Sf9 cells or of receptors that have been rendered constitutively active by site-directed mutagenesis, have provided an experimental system in which agonist-independent, spontaneous adenylyl cyclase activity can be measured. This phenomenon has been best characterized for the β_2 -adrenergic receptor but has also been observed for the bradykinin, dopamine D₁, and 5-HT_{2C} receptors, suggesting it is likely to be a general feature of the superfamily. A group of well-characterized β_2 -adrenergic receptor antagonists were found to inhibit, to varying degrees, receptor dependent spontaneous activity (17). Negative antagonists have been shown to promote the dissociation of spontaneously occurring receptor–G-protein interactions, using constitutively active mutant receptors. As an example, the ligand ICI118551 has been shown to inhibit the basal signaling activity of the β_2 -adrenergic receptor, thus acting as a negative antagonist (18).

Inverse agonist drugs may also span a range of activities, and thus current ligand and drug classification schemes recognize full agonists, partial agonists, neutral antagonists, and partial and full inverse agonists. For the ligand-gated ion channels, pharmacological studies of the interaction of the nicotinic acetylcholine receptor with a series of *N*-substituted analogs of decamethonium identified several compounds as antagonists but unique in their capacity to antagonize receptors that had been previously exposed to agonists. Through an extensive series of equilibrium and kinetic binding experiments, it was shown that these antagonists preferentially bound to the desensitized receptor state and had the ability to promote the conversion of the nicotinic acetylcholine receptor to this inactive state. In contrast, classical antagonists, such as tubocurarine, demonstrated the same affinity for both resting and desensitized receptor states. Antagonists that demonstrated enhanced affinity for the desensitized receptor state were termed metaphilic antagonists.

Noncompetitive Antagonists

Noncompetitive antagonists interact with a spatially distinct site (NCI site), which may be allosterically regulated by the agonist binding site(s) and block receptor function through an allosteric mechanism. In the absence of agonist, the allosteric constant, M , is increased by binding of these inhibitors, and in the presence of agonist, the rate of agonist-elicited conversion to the desensitized state is accelerated. For the LGCRs, the allosterically coupled NCI site is fundamentally different from the agonist site in its pharmacology. A study of the interaction of a phenylphenanthridium ligand, ethidium, with the high-affinity NCI site of the nicotinic acetylcholine receptor determined that it bound with extremely high selectivity to the desensitized state relative to a state stabilized by interaction with snake α -toxin at equilibrium, showing a ratio greater than 2800 (13). Conversely, ethidium binding at the NCI site and its occupation converted the receptor to a state of higher agonist affinity. Similarly, association rates for the binding of radiolabeled phencyclidine (PCP) to the NCI site increased by a factor of 1000–10,000 for the transient open-channel state relative to the toxin stabilized receptor state (19). Potential explanations for these findings are that the binding site location within the transmembrane ion channel is sterically inaccessible in a toxin-stabilized receptor conformation (Fig. 3) and that binding occurs only to selected conformational states, such as the open channel state (20). Numerous ligands act through allosteric mechanisms to regulate receptors in the LGCR superfamily. As in the case of the AChR, drugs such as MK-801 and PCP bind within the ion channel domain of NMDA receptors, blocking agonist-dependent activation. GABA_A receptor function is also regulated by the binding of benzodiazepines, barbiturates, and steroids at distinct allosteric sites on the receptor.

Methods to Study Drug–Receptor Interactions in Real Time

Drug–receptor interactions may quantitatively differ among rapidly converting multiple receptor states that are induced by agonist binding. While most studies commonly focus on analysis of ligand–receptor interactions and cellular responses under presumed steady-state conditions, experimental techniques available for the quantitative analysis of drug–receptor interactions with transient receptor conformational states are more limited. Since the actions of many receptors regulate rapid (within seconds) and transient changes in intracellular calcium and

protein kinase activity, the magnitude and the duration of the response to either transient or sustained agonist stimulation will determine the integrated cellular response. Thus, the effects of drugs on the temporal integration of individual receptor responses are critical in determining the response of a cell to extracellular stimuli.

Molecular pharmacological techniques have been applied to study rapid, real-time analysis of ligand–receptor conformational states and cellular signaling. A variety of rapid mixing techniques have provided sensitive and rapid measurements capable of defining receptor conformational transitions induced by agonist or drug binding to membrane-bound receptors. The earliest ligand–receptor kinetic studies measured radioligand binding of agonists and functional responses, using rapid filtration, but were technically limited in kinetic resolution. Direct spectroscopic measurements extending into the millisecond time domain have been made of conformational transitions for the nicotinic acetylcholine receptor (LGCR) and the formyl peptide (fMLP, GPCR) receptor because the affinity of fluorescent agonist ligands is greatly altered by interaction with their respective receptors (21). Real-time analysis of fluorescent formyl peptide ligand binding to intact human neutrophils by both spectrofluorometric and flow cytometric methods has led to a model of signal transduction dynamics and ligand–receptor–G-protein ternary complex interactions (22). Extrinsic fluorescence labeling of receptors by covalent modification of the receptors with reporter groups has also provided evidence for conformational changes in LGCRs and GPCRs. Spectroscopic signals originating from incorporation of an environmentally sensitive fluorescent probe into the purified, human β 2-adrenergic receptor provided kinetic information indicative of both agonist and negative antagonist-mediated receptor conformational changes (23).

Electrophysiological analysis of drug interactions with single receptor ligand-gated ion channels and voltage-dependent channels has provided another invaluable approach to analyze the activated open-channel states and closed states of LGCRs and voltage-activated ion channels with time resolution unmatched by other techniques. Using the methods of patch clamping, these high-resistance seals (gigaohm) attached to membrane patches or intact cells have recorded changes in conductance arising from the opening of individual transmembrane channels. Studies of this nature have been crucial in defining functional characteristics of many subtypes of receptor-ion channels and allowed the investigation of the mechanism of interactions of drugs with open channel states of these receptors, which are otherwise not amenable to study. In a classic study, the channel blocking mechanism of the local

anesthetic QX-222 with the nicotinic acetylcholine receptor was defined (24). Rapid and repeating flickering changes in conductance of one channel were observed as single drug molecules stochastically entered, blocked, and left the receptor ion channel. Kinetic constants derived from such measurements can define state-dependent blockade of receptor channels.

Flow cytometry has been utilized as a powerful approach to collect multiparameter kinetic data to evaluate multiple activation parameters simultaneously in individual cells and to correlate these parameters with the ligand occupancy of each cell. Cellular functional parameters that can be measured employing this technique include intracellular calcium, magnesium, pH, and membrane potential. Choices of functional parameters depend only upon the availability and utilization of a wide range of specific fluorescent probes that can act as reporters of the desired cellular parameter. Now a common procedure is to employ a fluorescent probe for calcium to measure continuous changes in intracellular calcium in populations of cells in suspension or in cellular monolayers of immobilized cells, using conventional spectrofluorometers. Utilized in combination with fluorescence digital imaging microscopy, spatial gradients reflecting changes in ion concentrations within individual living cells in the millisecond time domain have been visualized. New instrumentation has enabled adaption of this technique to a high-density plate format that is suitable for high-throughput screening in drug discovery programs.

Progress in defining the spatial and temporal cellular location of receptors in living cells during signal transduction has advanced through the use of confocal fluorescence microscopy coupled with the development of receptor-specific fluorescent probes. Receptor fluorescent probes, in particular, green fluorescent protein (GFP), have become a popular reporter molecule that has allowed measurements agonist mediated events in real time. Tagging of GPCRs with the GFP has enabled the direct visualization of real-time trafficking of GPCRs in living cells (11). The approach utilized has been to generate expression constructs that contains GFP fused to the carboxyl terminus of the receptor. Synthesis and expression of over 20 different GPCR–GFP chimeric fusion receptors has shown rapid changes in GPCR receptor cellular distribution in the membrane and the subsequent internalization of ligand and receptor. Such analyses have provided crucial insight into the mechanisms involved in controlling GPCR function and enable the studies of the actions of GPCR drug agonists. While basic receptor studies employing fluorescent ligands are still few, this nascent area is expanding as additional

specific fluorescent ligands, recombinant receptors, and instrumentation become widely available. These studies have also established fluorescence-based detection methods as the preferred format for ultrahigh throughput screening in drug discovery programs.

FUNCTIONAL ROLES FOR A MULTIPLICITY OF RECEPTOR SUBTYPES

The approach of molecular cloning has greatly expanded our knowledge of many receptor subtypes and has revealed an impressive heterogeneity of receptors not previously envisioned. The discovery of multiple receptor subtypes that are highly homologous has provoked examination of key questions related to their physiological functional significance and their importance as individual drug discovery targets. Substantial efforts have been made to define specific physiological roles and advantages conferred to the organism by expression of multiple receptor subtypes that have apparently identical endogenous ligand binding and signal transduction properties. Despite examples of receptor subtypes that exhibit indistinguishable binding and functional coupling properties, these closely related subtypes and isoforms may exhibit differences in properties that include the time course of activation, ionic selectivity, desensitization, regulation, and efficacy in coupling to distinct second messenger systems. Furthermore, homologous receptor subtypes within a family often display differentially regulated expression in particular cell types and tissues in response to specific stimuli.

Molecular Mechanisms Generating Diversity

Small differences in receptor structure (one to several amino acids) have been found to endow important pharmacological and functional differences to receptor subtypes and species homologs. Within the GPCR superfamily, a change in a single amino acid residue was found to underlie the major pharmacological differences between the rat 5-HT_{1B} and the 5HT_{1DB} receptors (25). Similarly, a change of one residue (Asn351Asp) in the dopamine D₅ receptor results in a 10-fold decrease in dopamine binding affinity while mutations in the D₂ receptor lead to differences in binding affinities for typical and atypical neuroleptic drugs used in the treatment of psychotic disorders. Essential differences in coupling of splice variants of the dopamine D₂ receptor, mglu1 receptor, somatostatin sst₂ receptor, and prostaglandin EP₃ receptor have been observed. Within the ligand-gated ion

channel superfamily, it has been found that the charge and size of a single amino acid residue in a critical channel site (the Q/R site of the GluR-B subunit) determines the particular ionic selectivity and permeability properties that characterize subtypes of AMPA-kainate-activated channels (26). For the muscle subtype of the nicotinic acetylcholine receptor, the functional properties of the receptor (channel conductance and open time) are altered during development by substitution of one of the subunits in the pentameric complex; from (α 1)₂ β 1 γ δ in embryonic muscle to (α 1)₂ β 1 ϵ δ in the adult muscle. Thus, the highly significant changes in receptor structure and function that can result from subtle variations in the genetic sequence encoding receptors can affect target identification, characterization, and validation in the drug discovery process.

Cellular and tissue expression patterns for related receptor subtypes may overlap but are often highly specific and tightly regulated. For example, there are striking differences in the cellular distribution of CXCR1 (IL-8R1) and CXCR2 (IL-8R2) receptors (77% sequence identity overall). CXCR1 expression is restricted to neutrophils, monocytes, and a few myeloid cell lines, whereas CXCR2 is widely distributed in myeloid cell lines but also in lymphocytes, melanoma cells, melanocytes, and fibroblasts (27). These specific cellular distributions suggest that the main function of the CXCR1 receptor is neutrophil activation and mobilization of phagocytes in host defense while the CXCR2 receptor serves to mediate migration and growth of cells not involved in defense. In situ hybridization studies of mRNAs encoding subunits of the neuronal nicotinic acetylcholine receptor gene family (LGCRs) and subtypes of GPCRs have documented that transcripts corresponding to homologous receptor subunits and subtypes within a receptor family exhibit distinct anatomical distributions in the mammalian brain (28). Among the family of human dopamine receptor subtypes, D₂ receptors are most highly expressed in the striatum, D₃ and D₅ receptors exhibit a preferential localization in the limbic area of the brain and low expression in motor areas such as the basal ganglia, while D₁ and D₄ receptors are both abundant in the cerebral cortex. Thus, the operative paradigm is that functional diversification and heterogeneity in expression patterns for receptor subtypes allows each subtype and isoform to perform a unique physiological role.

Defining Receptor Subtype Function

The process of defining receptor subtypes associated with cloned sequences and their associated physiological and pharmacological properties remains a major challenge,

particularly for the ligand-gated ion channel superfamily. The molecular diversity of subunits that comprise the nicotinic acetylcholine, GABA_A, and glutamate LGCRs families allows for a plethora of subtypes composed of unique heteromeric subunit combinations. Many of the subunits do not directly bind ligands but nevertheless dictate binding properties for the receptor complex. Expression of distinct combinations of subunits is required to understand the individual roles each subunit plays in creating pharmacologically distinct receptor subtypes when expressed in heterologous cells. Such expression studies have shown that recombinant GABA_A receptors composed of different α -subunit isoforms in combination with invariant β and γ subunits display distinct benzodiazepine pharmacology, GABA–benzodiazepine interactions, and steroid modulation. The existence of multiple receptor subtypes with unique pharmacological characteristics and differential subanatomical localization provides the rationale for their use as molecular targets in the development of novel subtype-selective drugs that are targeted to specific tissues and are hopefully devoid of the side effects associated with existing nonselective drugs.

CLONED HUMAN RECEPTORS AS DRUG DISCOVERY TARGETS

An important application of recombinant DNA technology has been the capability to provide human, cloned receptor subtypes as expressed functional proteins for drug discovery efforts. Prior to the availability of the cloned receptor targets, screening programs relied upon utilization of receptors obtained from animal tissue homogenates that had the inherent disadvantages of receptor heterogeneity, nonhuman pharmacology, and low receptor expression levels. The development and utilization of stable cell lines that express high levels of a single human receptor subtype for drug screening allow for a more accurate and selective pharmacological screening method compared with conventional methods and have enabled the discovery of highly selective drugs that discriminate between various receptor subtypes. Furthermore, cell lines have been engineered to express a recombinant receptor linked to a second messenger or other downstream biochemical response so that the functional consequences of receptor occupancy can be detected. Thus, not only can drug binding affinity of novel lead compounds be quantitatively defined, but the use of such recombinant cell lines permits rapid characterization of agonist or antagonist activity and measurements of compound efficacy at the cellular level.

Many human recombinant receptor subtypes expressed in a wide variety of human and other mammalian host cell backgrounds (e.g., CHO, HeLa, L-cells) have been found to exhibit ligand binding properties indistinguishable from their nonrecombinant “native” receptor counterpart. However, the use of recombinant receptor systems for receptor classification and pharmacological characterization can generate misleading data if heterologous host cell-specific properties have been imposed on the receptor. Ligand binding and signal transduction properties of many GPCRs have been found to depend upon the host cell as well as the expression level of the receptor, and thus agonist affinities and coupling mechanisms determined in different recombinant expression systems may not be identical. In the case of the expression of the human 5HT_{1A} in HeLa cell lines, certain compounds acted as agonists in a cell line with a high receptor density but acted as pure antagonists in a cell line with only a sixfold lower density of receptors. Similarly, data for other GPCRs have been obtained showing the dependence of agonist efficacy and pharmacological properties on receptor density.

The question of analyzing receptor function must be viewed within the context of the functional level for analysis as to whether the molecular entity is the single receptor, a signal transduction pathway, or an integrated cellular response. For example, activation of a specific signal transduction pathway is often viewed as a constituting a receptor response. Insight into the complexities of analyzing the responses of recombinant receptors in heterologous cells is provided by studies of the signal transduction properties resulting from the activation of the D₂ dopamine receptor stably expressed in two different cell lines. Activation of D₂ receptors in either GH₄C₁ rat pituitary cells or mouse Ltk[−] fibroblasts produced inhibition of adenylyl cyclase activity (29). However, while D₂ receptor activation caused a rapid stimulation of phosphatidylinositol (PI) hydrolysis and an increase in intracellular calcium in Ltk[−] cells, it failed to effect PI hydrolysis and induced a decrease in intracellular calcium in GH₄C₁ cells. Similarly, activation of the 5HT_{1A} receptor expressed in Ltk[−] cells was coupled to an increase in intracellular calcium but resulted in a decrease in calcium influx when expressed in GH₄C₁ cells. Since the cell-specific differences in the signaling pathways for the D₂ and 5HT_{1A} receptors were the same, these effects may most likely be attributed to the complement of G-proteins present in each host cell type. Thus, the effector systems and responses of a transfected receptor depend not only on the receptor but upon the particular cell type in which it is expressed.

The high level of membrane expression for recombinant GPCRs in insect cells (1–40 pmol/mg in Sf9 or Sf21

cells) using the baculovirus system has demonstrated appropriate receptor pharmacology for antagonist ligands (affinities and rank order potencies), whereas anomalous agonist binding properties and lack of functional coupling have been observed for some receptors. The GPCRs expressed using baculovirus typically show only a single, low-affinity binding state for agonists, whereas the same receptors demonstrate high- (coupled) and low-affinity (uncoupled) agonist binding states in mammalian cells. Similarly, the pharmacological properties of GPCRs expressed in yeast (M_1 muscarinic and D_2 dopamine receptors) were not comparable with mammalian cells since only a single low-affinity agonist binding state was detected, indicating that the recombinant receptors do not couple to the endogenous G-proteins present in these cells (30, 31).

Cellular engineering to coexpress recombinant GPCRs and the appropriate G-protein has been found to provide an approach to overcome such limitations. Toward this end, it was recently found that heterologous coexpression of the G protein α -subunit $G\alpha_{16}$ with a variety of GPCRs in mammalian cells enabled coupling to $PLC\beta$ activity and increases in intracellular calcium. In yeast, functional coupling was only achieved using a mutant strain lacking one yeast G-protein α -subunit and including a cDNA encoding an appropriate G-protein (31).

The integration of molecular biological approaches into receptor pharmacology has been useful in elucidating receptor structure–function relationships. Construction of chimeric receptors (hybrid polypeptides composed of adjacent portions of two related receptor subtypes) has helped to identify functional domains of many individual receptors. Such studies have successfully identified ligand-binding domains and cytoplasmic domains mediating signal transduction of many receptors. Using *in vitro* mutagenesis to change single amino acids to create point-mutated receptors has defined critical residues involved in receptor–ligand interactions, conformational transitions, ion channel selectivity, signal transduction, and sites of receptor phosphorylation. Due to the lack of high-resolution structural data for most membrane receptors, this approach often requires making the assumption that overall receptor conformation and the equilibrium distribution between receptor states (resting, active, and desensitized) have not been altered in the mutated receptor. Nevertheless, this experimental approach has been the basis for a large body of molecular modeling aimed at understanding the specific functional groups on receptors that interact with drug ligands. The combination of such molecular pharmacological and modeling approaches can be expected to reveal the structural determinants of drug binding and novel allosteric sites on

the receptor protein for drug interaction. Ultimately, the ability to produce large amounts of purified receptor protein from recombinant expression systems will enable the use of physical methods (NMR, electron microscopy,

Fig. 4 A molecular model of the dopamine D_2 receptor with a ligand docked in the binding site. The model of the D_2 receptor transmembrane helices was constructed from the coordinates of the bacteriorhodopsin structure derived from two-dimensional electron diffraction experiments and is consistent with the projection structure for rhodopsin. The transmembrane helices are represented by a solid ribbon and the drug, apomorphine, is a space filling representation. The top view looking down the helical axis of the receptor clearly delineates the seven transmembrane helices that are the key structural motif for the GPCR superfamily. Some of the helices are inclined relative to the perpendicular to the membrane plane. The bottom view is in the plane of the membrane with the extracellular space at the top of the figure. (Adapted from Ref. 57.)

X-ray crystallography) to obtain high-resolution receptor structural data that will delineate ligand-binding sites and precisely define drug–receptor interactions. The recent elucidation of the high-resolution structure of rhodopsin is a major step towards the detailed understanding of the 3D structures of the GPCR superfamily, as shown in Fig. 4 for the dopamine D₂ receptor.

Drug Discovery Using Adopted Orphan Receptors

There are now numerous examples of orphan receptors that have been identified as novel types or subtypes of existing receptor families for which functional roles have been characterized as proven therapeutic drug targets. Many of these orphan receptors are of immediate interest as potential drug discovery targets since they represent novel receptor subtypes that extend existing receptor families that have members that are therapeutically important drug receptor targets. The close structural relatedness that is the molecular basis for organization of the receptor superfamilies has allowed a rational-based search for new members of the ligand-gated ion channel, G-protein coupled, receptor tyrosine-kinase, and nuclear receptor superfamilies. In general, discovery of new receptors (or subunits) has been accomplished by screening cDNA libraries, using sequences conserved among the receptor family at low stringency (homology screening). An alternative method has been to employ PCR amplification of human genomic DNA with degenerate oligonucleotides encoding conserved receptor domains.

Initial efforts to identify orphan receptors exploited PCR methodology to clone several novel orphan receptors belonging to the GPCR superfamily (32). These orphan receptors were subsequently shown to include the adenosine A₁ and A_{2a} receptors (33), a 5-HT_{1D} receptor (34, 5), and a central cannabinoid receptor (CB₁). PCR using degenerate primers was subsequently used to identify cDNAs encoding the NK₁, NK₂, dopamine D₁ and D₅ (36), histamine H₃, adenosine A₃(37), olfactory receptors, and numerous other GPCRs. The application of these approaches has been highly successful and has led to the cloning of a series of orphan receptors (or novel subunits) in each superfamily for which functions have not yet been assigned. To date, more than 40 additional members of the nuclear receptor superfamily have been cloned for which ligands have not been identified. In addition, the ligands for the many orphan members of the receptor–protein tyrosine phosphatase superfamily have also not yet been established. Numerous orphan receptor–tyrosine kinases belonging to the EPH family have been identified that likely function by transducing signals

initiated by direct cell–cell interaction (38). Many of the EPH receptors are specifically expressed in the nervous system (39), and these receptors have been implicated in the control of axon guidance, in regulating cell migration, and in defining compartments in the developing embryo.

Strategies for Ligand Identification for Orphan GPCR Receptors

Since GPCRs constitute the largest superfamily of receptors in man and these receptors also represent important drug targets that have been subject to intense biochemical and pharmacological studies, the following discussion will focus on the orphan receptors that belong to the GPCR superfamily. An explosion of the number of orphan GPCRs has been primarily due to advances in both cloning and sequencing technologies. Specifically, directed studies employing a combination of low stringency hybridization, polymerase chain reaction, an increasing database of ESTs (expressed sequence and tagged cDNA) and high throughput sequencing technologies have led to an exponential increase in the number of orphan GPCRs that await ligand identification.

The new paradigm for orphan receptor-based drug discovery is shown diagrammatically (Fig. 5). A first step toward ligand identification for a given orphan GPCR is to generate a full-length clone if the cDNA sequence is incomplete. To accomplish this, a specific tissue is identified that contains the orphan receptor gene and a full-length cDNA clone is typically generated using RT-PCR. Next, the cDNA is fully sequenced, and the sequence is compared with the sequence of known GPCRs through the use of genomic databases. If the identity of an orphan GPCR approaches 45% with a known receptor, it is likely that the orphan receptor and the highly homologous GPCR will share the same ligand (40). Successful application of this approach led to the identification of the ligand for the human 5-HT_{1D}(41), C3a (42), and CGRP (43) receptors. However, there are subfamilies of GPCRs that do not show this degree of similarity. Furthermore, many orphan GPCRs may reveal no significant identity with known GPCRs but will demonstrate high homology to other orphan receptors, leading to the identification of new GPCR families, as typified by the important discovery of the edg family of lysophospholipid receptors (44).

Most orphan receptors share a low degree of overall sequence homology, which may be in the range of 20–30% overall amino acid identity. In these cases, a useful step in ligand identification is to evaluate the both the tissue and cell type distribution of the orphan receptor mRNA through Northern blot analysis or RT-PCR. A very

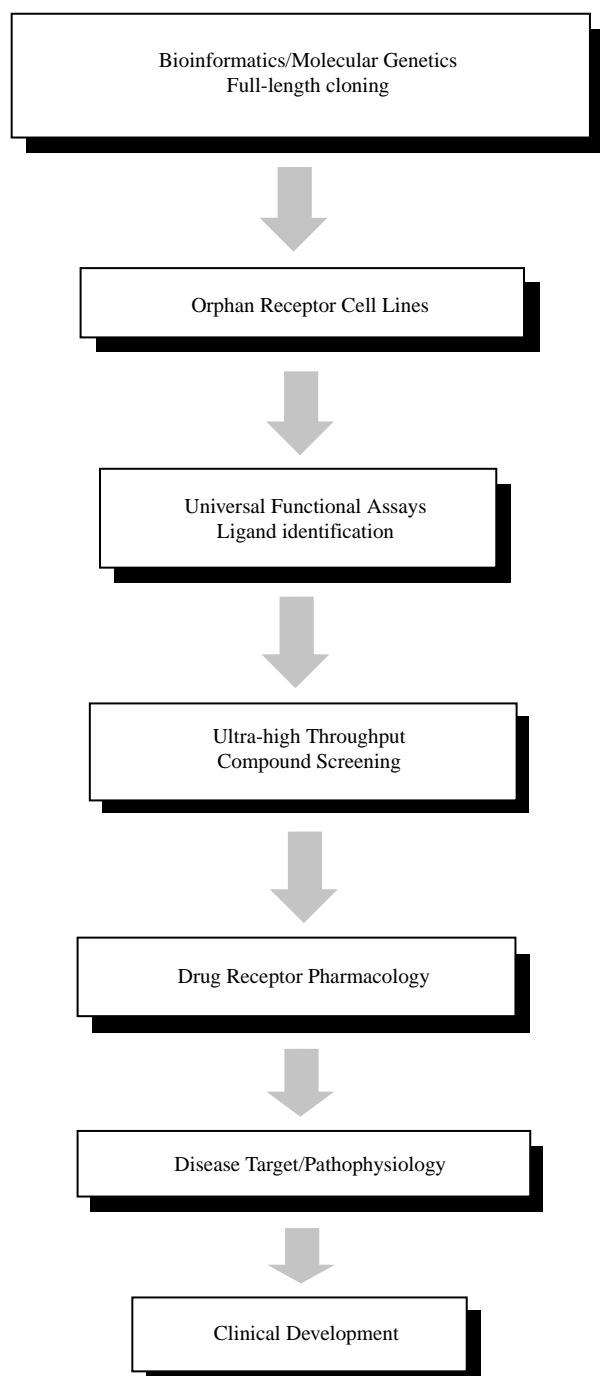

Fig. 5 Strategy for using orphan receptors as targets for drug discovery. The flow diagram illustrates the paradigm shift in receptor-based drug discovery, which is based upon a reverse molecular pharmacological strategy. The starting material for drug discovery is a sequence corresponding to an orphan receptor of unknown function.

restricted distribution pattern for an orphan GPCR may help provide clues concerning the physiological function of the receptor. Differential expression between normal and diseased tissue may indicate a role in the pathophysiology and suggest a potential therapeutic relevance for drugs targeted to the orphan receptor. Knowledge of the distribution of an orphan GPCR can also guide selection of cells or tissues to be used as sources of the endogenous cognate ligand for reverse pharmacology or ligand fishing studies. With the advent of chip technology, potentially thousands of orphan receptor cDNAs can be attached to a chip, thereby enabling the simultaneous evaluation of the expression levels under diverse pathological conditions.

Ligand Fishing for Orphan Receptors

Orphan receptors of interest may exhibit no significant homology with known GPCRs, and distribution studies may not provide any clues to the identity of the endogenous ligand. In this case, reverse pharmacology or ligand fishing studies are pursued (Fig. 5), especially for peptide receptors that often exhibit high affinity for their endogenous ligand. In this approach, the orphan receptor is used as bait to isolate the endogenous ligand from cell or tissue extracts suspected to contain the ligand (40, 44, 45). This approach has led to the discovery of novel endogenous peptide ligands orphanin FQ/nociceptin (46), orexin (47), prolactin-releasing peptide (48), melanin concentrating hormone (49), and APJ (50) as the cognate ligands for their respective orphan receptors. The specific high-affinity interaction of the endogenous ligand contained in extracts with the expressed orphan GPCR is measured in an appropriate functional second messenger assay. Once the active extract is identified, it can be fractionated, purified by HPLC, and the identity of the active component may be determined by analytical methods that may include peptide sequencing, mass spectroscopy, and NMR.

Expression of Orphan GPCRs

A critical step in ligand fishing for an orphan GPCR is to express the receptor in an appropriate cellular expression system. As previously discussed, choices may include mammalian cells, insect cells, bacteria, oocytes, or yeast. Initial considerations for choosing an expression system may focus on the type of functional assay to employ in screening procedures. A basic requirement for any given functional assay is the presence of the appropriate signal transduction machinery in the expression system. While it

is often not possible to predict specific coupling mechanisms and signal transduction pathways activated by an orphan receptor, several mammalian cells have been confirmed as suitable for human orphan receptor expression, including CHO and HEK 293 cells. All of these contain a full repertoire of signal transduction components required for measurement of most GPCR-mediated changes in second messenger systems (44). Another factor to be weighed in selecting an appropriate expression system is the potential interference of endogenous receptors present in the host cell line. This factor can be experimentally addressed through parallel screening of the parental cell line. Additionally, it is important to establish that the orphan receptor is expressed at sufficient densities and present on the membrane surface. Expression levels have been evaluated by epitope tagging of the receptor and measurement of receptor on the membrane surface by fluorescence activated cell sorting (FACS) or, alternatively, by Western blot analysis.

Functional Assays Used for Orphan Receptor Ligand Identification

For the full value of the receptor gene sequence to be realized, the function of the expressed orphan receptor, as well as its regulation and expression need to be elucidated. In many cases, exemplified by the nociceptin receptor, the orphan receptor will be activated by an as yet unknown endogenous ligand (transmitter, peptide, or hormone) or the endogenous ligand may be identified as a previously characterized molecule whose function has not been assigned. Strategies for identification of either the endogenous or surrogate ligands for an orphan receptor are frequently based upon utilization of high and ultrahigh throughput "agonist screening" assays in which ligand binding is coupled to a cellular functional response.

Functional assays based upon measurements of common cellular signal transduction pathways (i.e., mobilization of intracellular calcium, cAMP, transcription response elements) have been employed. Since many types of receptors (LGCRs, GPCRs, and RTKs) mediate cellular responses through elevations in intracellular calcium, real-time measurements of intracellular calcium, using fluorescent probes, have provided a rapid, generic assay for receptor activation. In addition, cell-based transcriptional activation assays represent a functional screening method that requires engineering of stable cell line(s) expressing the recombinant orphan linked to a luminescent or fluorescent-based reporter gene (i.e., luciferase or green fluorescent protein) under the

transcriptional control of a promoter element (i.e., cAMP response element (CRE), NFAT, or STAT binding elements). The advantages inherent in these one-step screening approaches include high detection sensitivity, compatibility with automation, and high throughput.

The first consideration for developing a functional assay for screening extracts or compounds to identify endogenous ligands or surrogate agonists for orphan GPCRs is to determine which G-protein(s) mediate coupling to the receptor. Certainly, this is difficult to determine unless the orphan receptor of interest contains a high level of homology to other known GPCRs activating well-characterized signal transduction pathways. In some cases, evaluation of extracts or compounds in both G_s , G_i and G_q -associated functional assays is necessary. Once the type of assay endpoint is chosen, there is a variety of high throughput and robust functional assays that can be utilized in ligand fishing. Advances in commercially available technology have enabled the development of ultrahigh throughput screening methods and systems that have led to the miniaturization of assays from 96-well plate formats to 1536-well formats that require only microliter volumes of reagents. Functional assays based upon one of several fluorescence detection techniques, including fluorescence resonance energy transfer, polarization, time-resolved fluorescence, and luminescence, now allow receptor-activated signaling events in live cells to be rapidly measured.

Reporter gene assays

Reporter gene assays have been widely used as high-throughput, cell-based functional assays for numerous GPCRs. In these assays, gene transcription is activated by a receptor-associated transduction event, such as increases in cellular cAMP or intracellular calcium. Reporter genes typically consist of a specific responsive element placed upstream of a minimal promoter, which together control the expression of the reporter gene, such as β -galactosidase luciferase. Commonly used response elements include the cAMP response element that is suitable for either G_s - and G_i -coupled receptors or a calcium-sensitive response element suitable for G_q -coupled receptors (51).

Another cell-based functional gene transcription assay has been developed by Tsien and co-workers that permits real-time receptor activation of gene expression to be measured in live cells. For this assay, mammalian cells are transfected with receptor and the gene for β -lactamase that acts as a reporter by hydrolyzing an exogenous substrate that is loaded intracellularly. The highly sensitive fluorescence assay permits clonal selection of single cells by flow cytometry and forms the basis for a high-throughput screen.

A bioluminescent reporter assay for G_q -coupled receptors has been described in which the receptor of interest is cotransfected with the calcium-sensitive protein aequorin. Agonist activation of receptor-mediated increases in intracellular calcium lead to activation of aequorin and subsequent luminescent responses (52). Due to the considerable amplification occurring after agonist activation of the GPCR, this assay can be significantly miniaturized and run in 96-, 384-, and 1536-well formats. Transient expression of apoaequorin in CHO cells and reconstitution with the co-factor coelenterazine resulted in a large, concentration-dependent agonist-mediated luminescent response following cotransfection with the endothelin ET_A , angiotensin AT_2 , thyrotropin-releasing hormone (TRH), and neurokinin NK_1 receptors, all of which interact predominantly with the G_{α_q} -like phosphoinositidase-linked G-proteins. To generate a system amenable for the study of agonist activity at virtually any G-protein-coupled receptor, the α -subunit of the receptor promiscuous G-protein $G_{\alpha_{16}}$ was either transiently or stably expressed in CHO cells together with apoaequorin. In cells expressing $G_{\alpha_{16}}$, but not in its absence, agonists at a series of receptors that normally interact with either G_{α_s} or G_{α_i} were now able to cause a luminescent response from mitochondrially targeted apoaequorin. In the case of the A_1 adenosine receptor, this response was clearly a result of activation of $G_{\alpha_{16}}$ and not a consequence of the release of the G_{α_i} -associated β/γ complex, as the luminescent response was unaffected by pertussis toxin treatment of the cells, whereas agonist-mediated inhibition of adenylyl cyclase activity was attenuated. These studies describe the use of coexpressed apoaequorin as a reporter for G-protein-coupled receptor-mediated calcium signaling. Furthermore, coexpression of $G_{\alpha_{16}}$ and apoaequorin provides a basis for a generic mammalian cell microplate assay for the assessment of agonist action at virtually any GPCR, including orphan receptors for which the physiological signal transduction mechanism may be unknown.

Use of Engineered Cells for Developing Cell-Based Functional Assays

Advances in molecular engineering have facilitated the design of recombinant cells that can be used to design universal assays for orphan receptors. As a tool to analyze the function of newly discovered orphan receptor genes, "promiscuous" G-proteins have been utilized to develop screens for orphan GPCRs that can be used to search for compounds that activate such receptors. For example, coexpression of the "universal adapter" $G_{\alpha_{16}}$ G-protein with an orphan GPCR of interest allows the activated

receptor to couple to increases in intracellular calcium, although the receptor may not couple to G_q in nonengineered cells. Another common approach to designing a universal functional ligand-screening system for any GPCRs is to construct and coexpress chimeric G-proteins with an orphan GPCR (53). Chimeric G-protein α -subunits have been constructed in which the backbone of either G_s , G_i , or G_q , is combined with small peptidic sequences corresponding to the C-terminus of G_s , G_i , and G_q . The C-terminal end of the chimera dictates receptor coupling and the G-protein backbone determines which effector system is activated. For example, short C-terminal portions of G_s or G_i can be combined with the backbone of G_q , resulting in an engineered G-protein chimera that can universally signal through increases in intracellular calcium or activate calcium sensitive reporter assays (53, 54). Conversely, chimeras can be constructed with the backbone of the G_s - α -subunit and the C-terminus of G_q to develop an assay system in which cAMP is measured. The design of universal assay systems for orphan GPCRs can greatly facilitate throughput for analysis of large numbers of candidate receptors.

Recently, a number of GPCRs have been reported to activate second messenger responses, even in the absence of their natural ligands or surrogate agonists. GPCRs that possess this ligand-independent activity are referred to as constitutively active GPCRs. Three different methods have been employed to produce constitutively activated receptors and include: 1) overexpression of the native receptor in heterologous expression systems, 2) overexpression of the appropriate G-protein that couples to the receptor, or 3) mutation of specific aminoacid residues of the receptor, typically in transmembrane regions or in intracellular loops of the receptor. A number of pharmaceutical companies are now utilizing constitutively activated orphan GPCRs for identification of either inverse agonists or agonists from small molecule libraries using functional ligand-independent screens. Thus, drug discovery for orphan GPCRs does not now require previous identification of the endogenous ligand or a surrogate agonist to develop a functional screen for drug discovery. Molecules discovered in these screens can be used not only as potential therapeutics but also as tools to further evaluate the physiological functions of the orphan GPCRs and their potential therapeutic relevance.

Screening for Endogenous and Surrogate Ligands

After a reliable and robust functional assay is developed for an expressed orphan receptor, screening can ensue.

Several approaches can be taken. First, cell and tissue extracts or biological fluids can be evaluated for activation of the orphan receptor. If an active extract is identified, it is further fractionated and then subjected to HPLC followed by further testing of fractions in the functional assay. After substantial purification, the identity of the active component can be elucidated by numerous analytical methods including mass spectroscopy and NMR. Another approach is to screen a collection of compounds with known pharmacological actions and biological compounds for which the mechanism of action is unknown. A third approach is to screen peptide or small molecule libraries. This can easily be accomplished rapidly due to advances in high-throughput screening and laboratory automation. Once the surrogate ligand is identified, clues as to the physiological function of the orphan receptor and possibly the endogenous ligand can be often obtained.

The identification of gene sequences is only the beginning of the process for the development of the useful small molecule therapeutic agent. Analysis of a stretch of only 10–25 amino acids from an orphan receptor sequence may be sufficient to identify whether the orphan of interest is homologous to either a known protein or a recognizable motif that corresponds to a ligand recognition or functional domain characteristic of a receptor superfamily. Based upon the level of observed sequence homology with known receptors, it may be possible to either deduce the class of ligand bound by the orphan receptor and/or postulate a mechanism of signal transduction. The systematic search for natural cognate ligands of orphan receptors is more difficult when the properties of such receptors are not well predicted by sequence comparisons to known receptors and/or the orphan receptors exhibit novel pharmacology.

As an example of the first strategy, the process leading to the characterization of the orphan ORL1 (Opioid Receptor-Like I) receptor, which has become known as the orphanin or nociceptin receptor (46), is of interest since it represents one model that can be readily adapted to other orphan receptors. The ORL1 receptor is a novel G-protein coupled receptor that is most closely related to the opioid receptors. Based upon substantial sequence identity of the ORL1 receptor with opioid receptors (50% overall, 65% within transmembrane domains), it was reasonable to hypothesize that the related orphan receptor would share signal transduction properties in common with the μ -, δ -, and κ -opioid receptor subtypes. Since opioid receptors are all negatively coupled to adenylyl cyclase, a stable recombinant CHO cell line expressing ORL1 was constructed for use in a functional screen, using untransfected CHO cells as a control. A survey of opiate ligands identified etorphine, a nonselective opiate agonist, as mediating inhibition of forskolin-induced accumulation

of cAMP, although its potency was found to be about three orders of magnitude less compared with other opioid receptors. However, additional efforts to characterize the pharmacology of the ORL1 receptor by analysis of agonist effects induced by endogenous opioid peptides (endorphins, enkephalins, and dynorphins) or other synthetic opioid ligands were not successful.

Based upon the structural homology of ORL1 with opioid receptors, in particular, the acidic extracellular loop 2 of the κ -opioid receptor, it was hypothesized that the endogenous ligand might be a peptide that resembled dynorphin. A biochemical fractionation procedure was used to isolate a pituitary peptide whose structure was identified as a 17 amino acid neuropeptide that shares many features in common with other opioid peptides and is now known as nociceptin. Isolation of the endogenous ligand was achieved through a functional assay on the basis of its ability to inhibit adenylyl cyclase in a stable recombinant cell line. The identity of nociceptin was confirmed through synthesis of a radiolabeled derivative that was found to bind in a saturable manner with high affinity and to be a potent and specific activator of the ORL1 receptor. In vivo activity of nociceptin induced hyperalgesia when administered intracerebroventricularly to mice, indicating the agonist of the ORL1 receptor appears to possess pronociceptive properties. The unique pharmacology, physiology, and brain distribution of this novel receptor make it an important target for drug discovery.

An alternative approach may be to employ an immobilized orphan receptor to capture the cognate ligand from biological extracts, fractions, and other combinatorial chemistry libraries. Orphan receptor screening efforts will be able to take advantage of large-scale synthetically produced random peptide, peptidomimetic, and combinatorial chemical libraries, as well as phage display libraries that are available as novel sources of chemical and structural diversity for discovery of potent and selective chemical entities for each of the receptors. Finding new natural product-based lead compounds by screening fermentation broths and extracts from plant and marine organisms may yield ligands with novel structures, as was found in the case of the subtype-selective endothelin receptor peptidic antagonists.

Among the GPCR superfamily, the discovery and characterization of the large number of novel receptor subtypes belonging to the chemokine, dopaminergic, serotonergic, somatostatin, and opioid receptor families provide examples of the tremendous impact of gene cloning. As a consequence of the original cloning of the orphan receptor sequence corresponding to the 5-HT_{1D} receptor in 1989 (55), the human receptor sites involved in the action of acute antimigraine drugs were subsequently

identified. Studies of these receptors have led to significant insights into the pathophysiology of migraine and the development of new antimigraine drugs, such as naratriptan and zolmitriptan, which were selected for development based upon their high affinity and selectivity for the human recombinant 5-HT_{1D} receptors. Clearly, the value inherent in orphan receptor characterization for drug discovery has been proven and will continue to lead to the discovery of substantial numbers of novel, human receptors designated as “orphans” that will provide novel targets for drug development.

Human Genome Sequencing—New Orphan Receptors and Subtypes

The most intensive research project in biomedicine is under way—the immense task of sequencing the human genome and identifying all of the expressed human genes. This effort is driving a paradigm shift in the fundamental approach to drug discovery as genomic data becomes the initiation point for the drug discovery process. Considerable progress has been made by the Human Genome Project as advances in cloning, mapping, and sequencing technologies have jointly contributed to an explosion in the volume of human sequence data. The rapidly approaching completion of the human genome sequence will lead to structure of all of the roughly 25,000–35,000 different human genes. To integrate and analyze the vast database of genomic data, the field of bioinformatics is providing powerful computational algorithms and methods for searching databases and complex data sets to allow molecular classification and extrapolate receptor structure and function from numerous new sequences. The impact of this effort will be an exponential increase in the number of novel orphan receptors requiring further study to define their potential role as targets for drug discovery. At the conclusion of this project, the identification and sequence of all receptor genes in the human genome will be available for study. Based upon estimates that 2–3% of the genome is likely to consist of receptors, this would suggest that the total number of receptors to be identified will be approximately 600–900. Yet another benefit of these genomic efforts will be the identification single disease-causing genes that are responsible for common or inherited diseases. Numerous examples exist for disease states that are associated with either deficient receptor responses, unregulated signaling function, or enhanced responses to neurotransmitter or hormonal signaling, indicating the biomedical importance for identifying the molecular etiology of a disease state and gaining access to disease-relevant receptor targets. The recent cloning of a Kaposi's sarcoma-associated herpesvirus (KSHV, or

human herpesvirus 8) genome fragment revealed an open reading frame encoding a putative GPCR that was homologous to human CXCR1 and CXCR2 receptors (56). Expression studies showed that it was indeed a bona fide signaling receptor that exhibited binding characteristics of a chemokine receptor, with affinity for a range of chemokines in the CXC and CC families. The receptor demonstrated constitutive (agonist-independent) activity in COS cells and stimulated cellular proliferation, making it a candidate viral oncogene.

Technological extensions based upon the human genome sequencing platform that enhance receptor-based drug discovery include development and construction of biochips containing DNA microarrays of gene sequences. These biochips enable high-throughput screening using fluorescent hybridization of total cDNA or mRNA libraries from particular cell types or rare tissues and permit quantitative examination of large numbers of specific receptor sequences expressed in normal and disease samples. The large-scale quantitative examination of large numbers of specific receptor sequences expressed in normal and disease samples is called expression profiling. Such differential gene expression studies can detect different levels and patterns of a receptor gene expression in different tissue states and can be used as a tool to decipher receptor gene function and potentially define a relationship to a particular disease state.

In summary, the application of molecular genetics to large-scale sequencing, analysis of DNA sequence information, and new experimental approaches for rapid functional analysis of receptor molecules from these sequences can be expected to lead to the identification of an abundance of novel receptors that will become molecular targets for the development of highly selective drugs. Indeed, gene-based discoveries are already providing an entirely new approach to the development of a novel drug pharmaceuticals. The parallel utilization of all receptor subtypes that comprise a family of human receptors in high-throughput primary screening programs has demonstrated the value of this approach for the identification of receptor-subtype specific drugs. This development in the field of drug discovery holds great promise since drugs with therapeutic activity that emerge from such screening programs should possess high molecular specificity.

The current challenge in receptor functional genomics will be to develop successful experimental strategies and new technologies for the identification of ligands that can activate orphan receptors or inhibit these receptors, should they exhibit constitutive, basal activity. Although progress has been made, the continued application of molecular biological approaches to receptor pharmacology coupled with advances in biophysical methods should serve as

tools that will enable a precise delineation of receptor binding sites and drug–receptor interactions at the molecular level. A more complete understanding the molecular events that transduce ligand binding into receptor activation will ultimately aid in the discovery of more selective agents for specific conformational states of existing receptor subtypes. Furthermore, the rapid elucidation of receptor–protein interaction partners and mapping intracellular signal transduction pathways associated with receptor signaling will accelerate understanding of novel receptor function. Finally, methods to localize and image the expression of receptor genes in living cells and animals can be expected to provide a foundation for novel pharmacological interventions targeted to specific cell types and tissues.

The application of many new technologies is synergistically accelerating the process of moving from novel receptor gene sequences to validated drug discovery receptor targets and ultimately, new drugs. The ongoing sequencing of the human genome and ensuing characterization of orphan receptors coupled with the precise molecular analysis of receptor structure, function, expression, and role of these receptors in disease processes will continue to reveal new drug receptor targets that will serve as a platform for much of the drug discovery enterprise.

Rheology of Pharmaceutical Systems

Fridrun Podczeck

University of London, London, U.K.

INTRODUCTION

The American Society of Rheology, which was founded in 1929, has defined “rheology” as the science of deformation and flow of matter. Deformation describes the change of matter in terms of shape or volume, or both. If the changes due to deformation are at least partly nonreversible, then matter flows. The full spectrum of possible types of deformation of liquid or solid matter is illustrated in Fig. 1. The gaseous state is usually not part of rheological investigations.

Typical modern rheological investigations do not consider Newtonian liquids in the sense of the Navier–Stokes model or fully elastic solids, but are concerned with the behavior of materials between these two extremes.^[1] In the pharmaceutical sciences, however, Newtonian behavior and its characterization are of interest, and methodology and equipment are described in various pharmacopeias to provide standards for the quality of pharmaceutical materials.

There is an increasing interest in rheological methods in the medical and biological sciences. A change of the rheological behavior of certain body fluids such as mucus,^[2,3] saliva,^[4] blood,^[5–7] or synovial fluid could be used as an indicator of the severeness of a disease or the effectiveness of drug substances used to treat certain medical conditions such as mucoviscidosis. The rheological properties of raw materials and formulations can cause problems during the manufacture of dosage forms in the pharmaceutical, cosmetic, or food industry. For example, more viscous materials require larger amounts of energy during mixing. The viscosity might be reduced by the application of heat, which could reduce the mixing time and improve product homogeneity. However, gel–sol transformations are not always reversible, and in some instances, the heat development due to shear might already destroy the product. Transport and handling might also result in a change in viscosity of the product.^[8] A decrease of the viscosity of suspensions could hence result in increased sedimentation and, for example, hard shell capsules containing a thixotropic filling might start to leak.

The rheological properties of pharmaceutical products are also important with respect to patient compliance. Stiff creams might complicate their application or could cause pain, and hence the patient will be more reluctant to use his medicine. Suspensions and emulsions should flow out of the bottle to allow easy metering and, for example, toothpaste should be squeezed out of a tube easily, yet should form a string without leakage of fluid. Several injections rely on gel–sol transformation, for example, those containing aluminum stearate. Aluminum stearate is added to produce a stiff gel for prolonged-release delivery of antibiotics via intramuscular injection. To ease the pain involved, the gel should form a sol solely on shaking, yet after injection gelation should occur quickly to maintain the prolonged-release principle. Hence, the knowledge of rheological techniques can play an important role in pharmaceutical development and manufacture.

DEFINITIONS AND TERMINOLOGY

Stress and Strain

Deformation is the result of a force acting on or within a body, yet its extent depends not on the force itself, but on the magnitude of force per unit area, i.e., the stress (unit: Pa or N m^{-2}). Forces acting within a body are the result of gravity or inertia and are effective throughout the whole body. Surface forces act on defined points along the periphery of the material.

As a consequence of the stress applied, the body will change its shape, and as a result, there will be a change in length of the body, i.e., strain. The relationships between stress and strain are illustrated in Fig. 2.

In many of the rheological test methods, the sample is subjected to “simple shear.” The best example for illustration is that of a pack of cards (Fig. 3). If a shear stress τ is applied to the top (“reference”) card of the pack, the displacement of each individual card of the pack is proportional to its distance from the reference card. The larger the distance is, the less is the card displaced. The relative displacement of two cards divided by their separation ($\delta l/l$) is called “simple shear strain.”

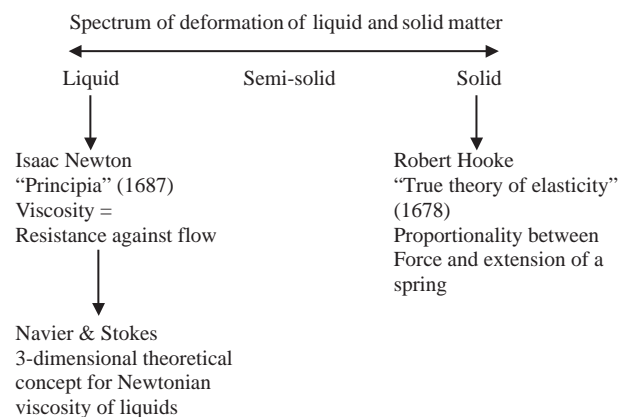

Fig. 1 Spectrum of deformation of liquid (viscous) and solid (elastic) matter first described by Newton and Hooke, and further developed by Navier and Stokes. Semisolid matter behaves viscoelastic, i.e., viscous at low strain rates and elastic at high strain rates.

Rate of Strain and Shear Rate

The rate of strain ("strain rate") considers the magnitude of the changes in length as a function of time (unit: sec^{-1}). For the tensional strain, the strain rate is hence defined as $\dot{\epsilon} = d\epsilon/dt$, whereas the shear strain rate ("shear rate") is defined as $\dot{\gamma} = d\gamma/dt$ (for symbols refer to Fig. 2). In simple shear, the shear strain rate can be explained as the velocity gradient occurring in a sample during flow.

Fig. 2 Definitions and relationships between stress and strain: the vectors of normal force (solid line) and normal stress (dashed line) are in one and the same direction, whereas these vectors are orientated perpendicular in shear.

Fig. 3 Simple shear illustrated on a pack of cards: τ = shear stress, l = distance between two cards, δl = displacement of two cards relative to each other.

However, in cases where the flow lines are curved, the velocity gradient is not equal to the shear strain rate. Such complicated flow can happen in concentric cylinder viscometers (e.g., "cup and bob viscometer"), in particular at higher angular velocities and with the inner cylinder rotating ("Searle principle").^[9] Centrifugal forces stabilize the flow when the outer cylinder rotates ("Couette principle"), and turbulent flow is hence less likely.^[10] In cone-plate viscometers, deviations from laminar flow are sufficiently suppressed when using small cone-plate angles^[11] as is done in most practical instruments.

Modulus of Elasticity and Compliance

In the ideal case of a Hookean body, the relationship between stress and strain is fully linear, and the body returns to its original shape and size, after the stress applied has been relieved. The proportionality between stress and strain is quantified by the modulus of elasticity (unit: Pa). The proportionality factor under conditions of normal stress is called modulus of elasticity in tension or "Young's modulus" (E), whereas that in pure shear is called modulus of elasticity in shear or "modulus of rigidity" (G). The relationships between E , G , shear stress, and strain are defined by:^[12]

$$G = \frac{E}{2(1 + \nu)} \quad (1)$$

$$\gamma = \frac{\tau}{G} \quad (2)$$

where ν is the Poisson's ratio. For soft solids and liquids, where the stress needed to change the shape is considerably smaller than the stress required to change the volume, Poisson's ratio is approximately 0.5.^[10] Hence, $E \approx 3G$.

The moduli of elasticity in tension and shear are important for viscoelasticity measurements, where the stress applied is small.

The compliance is defined as the reciprocal of the modulus of elasticity (unit: Pa^{-1}). Hence, shear compliance is defined as $J = 1/G$, while tensile compliance is defined by $D = 1/E$.

Viscosity

The flow of liquids or semisolids is described by viscosity, or, more precisely, by shear viscosity η (unit: Pa sec). The viscosity defines the resistance of the material against flow. Viscosity is not a coefficient, because it is a function of the shear strain rate $\dot{\gamma}$ [$\eta = f(\dot{\gamma})$]. In the classical fluid mechanics, the dynamic viscosity is obtained using a viscometer. (A viscometer is a rheometer, i.e., an instrument for the measurement of rheological properties, limited to measuring the viscosity only.) The ratio between dynamic viscosity and material density is termed “kinematic viscosity” ($\nu = \eta/\rho$; unit: $\text{m}^2 \text{sec}^{-1}$). The kinematic viscosity provides a normalized value and characterizes the flow velocity. In the engineering sciences this value is, for example, used to calculate the throughput of liquids in pipes.

The reciprocal of the viscosity is called “fluidity” (unit: $\text{Pa}^{-1} \text{sec}^{-1}$) and is an indicator of the mobility of the material.

TYPES OF RHEOLOGICAL BEHAVIOR IN SIMPLE SHEAR

Newtonian Flow

The relationships between stress, strain, and viscosity are usually depicted in the so-called rheograms. In the pharmaceutical sciences, typical flow curves are presented, i.e., $\tau = f(\dot{\gamma})$. In the engineering sciences, the viscosity is usually drawn as a function of the shear stress [$\eta = f(\tau)$]. This is sensible as most viscometers control the shear stress applied rather than the shear strain rate. However, the entity of interest is the viscosity as a function of the shear strain rate [$\eta = f(\dot{\gamma})$].

In the following text, descriptions such as “liquid,” “fluid,” or “semisolid” have been avoided where possible to stress similarities and differences in the rheological behavior of matter.

Newtonian behavior can be observed only for ideally viscous bodies. The flow curve shows a direct proportionality between shear stress and shear strain rate (Fig. 4a) with the straight line going through zero. The viscosity remains constant over the complete range of shear stresses applied and is independent of the shear strain rate (Fig. 5a). The stress in the material goes back to zero immediately

Fig. 4 Typical rheogram of a Newtonian (a) and a Bingham body (b).

when shearing has stopped, and repeated shearing always results in the same value of viscosity. Even after extended shearing times, the viscosity of Newtonian bodies does not change. Hence, for Newtonian bodies, the viscosity is a material constant at a given temperature and pressure. Many liquids such as water, glycerol, fatty oils, or organic solvents behave like Newtonian bodies. Also molten Vaseline behaves Newtonian, whereas at room temperature Vaseline is classified as a non-Newtonian body. While many liquid materials behave ideally viscous, their mixtures often show non-Newtonian behavior.

Non-Newtonian Flow

Shear thinning (“pseudoplastic flow”)

Shear thinning materials show a decrease in viscosity with increasing shear strain rate. A typical flow curve is

Fig. 5 Viscosity as a function of shear strain rate for a Newtonian (a) and a Bingham body (b).

presented in Fig. 6a, and the viscosity as a function of shear strain rate is depicted in Fig. 7a. The curves indicate that at very low shear stress values/shear strain rates and again at very high shear stress values/shear strain rates, the viscosity reaches a constant value. These two regions are often referred to as lower (i.e., lower shear strain rate) and upper (i.e., higher shear strain rate) Newtonian regions. The viscosity representing the lower Newtonian region is also known as the “zero-shear viscosity.” The upper Newtonian region cannot be obtained experimentally in some instances due to the limitations of some older equipment.

Shear thinning is often observed in solution containing thread-like macromolecules such as celluloses or unbranched polymers. Here the stress applied causes the macromolecules to align in the direction of the shear stress vector. This results in a reduced resistance to flow, and hence in a decrease in viscosity. After the orientation process is complete, the solution shows Newtonian flow.

Mathematical models, which can predict the shape of a flow curve of a shear thinning material including lower and upper Newtonian regions, require at least four parameters. The Cross model^[13] is one such model:

$$\frac{\eta - \eta_\infty}{\eta_0 - \eta_\infty} = \frac{1}{[1 + (K\dot{\gamma})^m]} \quad (3)$$

where η_0 and η_∞ are the asymptotic values of viscosity in the lower and upper Newtonian region, K is a constant with the dimension of time describing the steepness of the curve, and m is a dimensionless constant describing the overall curvature. Examples of a successful application of the Cross model to aqueous solutions of macro-

Fig. 6 Typical rheogram for a shear thinning (a), shear thickening (b), and a Casson body (c).

Fig. 7 Viscosity as a function of the shear strain rate for a shear thinning (a), shear thickening (b), and a Casson body (c).

molecules can be found by Boger^[14] and Whitcomb and Macosko.^[15]

Carreau^[16] devised another general equation to model the shear thinning behavior, which has become a popular alternative to the Cross model:

$$\frac{\eta - \eta_\infty}{\eta_0 - \eta_\infty} = \frac{1}{[1 + (k_1\dot{\gamma})^2]^{m_1/2}} \quad (4)$$

The constants k_1 and m_1 are of similar importance for the shape of the flow curves as are K and m in the Cross model.

In acknowledging that the upper Newtonian region is sometimes not observed due to experimental difficulties, the Cross and the Carreau models reduce to Eqs. 5 and 6, respectively:

$$\frac{\eta}{\eta_0} = \frac{1}{1 + (K\dot{\gamma})^m} \quad (5)$$

$$\eta = \frac{\eta_0}{[1 + (k_1\dot{\gamma})^2]^{m_1}} \quad (6)$$

Similarly, the two models could be reduced by neglecting the lower Newtonian region. This has been done by Sisko^[17] for the Cross model in order to account for the rheological properties of grease in bearings:

$$\eta = \eta_\infty + \frac{\eta_0}{(K\dot{\gamma})^m} \quad (7)$$

Other practical applications for the Sisko model have been reported for yogurt^[18] and polymer liquid crystals.^[19]

Considering that in many cases the viscosity measured is significantly smaller than that of the lower Newtonian region ($\eta \ll \eta_0$), and significantly larger than that of the upper Newtonian region ($\eta \gg \eta_\infty$), the Cross model can be further simplified:

$$\eta = \frac{\eta_0}{(K\dot{\gamma})^m} \quad (8)$$

It is standard practice to redefine the constants so as to $m = 1 - n$ and $\eta_0/K_m = K_2$.^[1] Using these definitions in Eq. 7 provides the so-called “powder law” model:

$$\eta = K_2 \dot{\gamma}^{n-1} \quad (9)$$

where n is the power law index, and K_2 is the consistency. The latter has the units of Pa sec^n and is hence difficult to interpret in physical terms. The larger the values of K_2 are, the stiffer the materials appear at rest. The value of n describes the curvature of the flow curve. Values of n below unity are found for shear thinning non-Newtonian bodies, whereas a value of 1 would be found for Newtonian flow. It should also be noted that Eq. 9 only describes the shear thinning region of a flow curve without considering the possible existence of a lower or upper Newtonian region.

Shear thickening (“dilatant flow”)

Shear thickening materials show an increase in viscosity with increasing shear strain rate. An idealized flow curve is presented in Fig. 6b, and the viscosity as a function of shear strain rate is depicted in Fig. 7b. The shear thinning region usually extends only over about one decade of shear rate (power law index $n > 1$) in contrast to shear thinning, which usually covers at least two or three decades. Also, in many cases, shear thickening is preceded by a short phase of shear thinning at low shear strain rates.^[1,20]

Shear thickening is typical for the flow of pastes and suspensions, when these have high concentrations of solid particles. However, the particle size needs to be below $50 \mu\text{m}$. The minimum solid concentration is usually quoted to be more than 50%, and suspensions show shear thickening if they are deflocculated. At rest and low shear the particles are covered with a liquid film coating acting as a lubricant. At low shear strain rates this liquid flows showing shear thinning. However, the liquid layer will be disrupted above a critical stress. Solid particles come into close interparticulate contact, which results in friction and hence in an increase in viscosity, i.e., shear thickening. Hoffman^[21] has studied this effect in more detail using an optical diffraction system.

Complex Flow Behavior

Bingham bodies

Newtonian flow, shear thinning, and thickening represent comparatively simple flow patterns. The description of flow becomes more complex, if these flow patterns occur in combination with a yield stress, i.e., a minimum stress required for flow to be visible in an adequately short time span. The observation of a yield stress is mostly related to the existence of a defined inner structure such as that of Vaseline or cubic liquid crystals.

Doubt has been cast on the existence of a true yield stress a long time ago, and it is usually Professor Reiner, who is quoted to have said “everything flows if you wait long enough,” some 60 years ago. Barnes and Walters^[22] found an apparently well-defined yield stress for PVA latex adhesives employing a shear strain rate-controlled rheometer. However, when they lowered the mean shear strain rate, the yield stress decreased proportionally. Finally, when they measured these materials at extremely low shear strain rates using a stress-controlled rheometer, Newtonian flow and absence of a yield stress was observed. Hence, it might be better to quote an “apparent” yield stress valid for defined experimental conditions only.

The Bingham body model describes materials with an apparent yield strength above which Newtonian flow is observed. This is illustrated in Figs. 4b and 5b, which show a typical flow curve and viscosity as a function of shear strain rate, respectively.

Flocculated suspensions often have high viscosities at low shear strain rates, which give the impression of the existence of a yield stress.^[23] The nearly Newtonian flow observed is due to a dramatic reduction in the effective number of particles as a result of the particle association process.

Mathematically, the Bingham body can be described as:

$$\tau = \tau_Y + \eta_P \dot{\gamma} \quad (10)$$

where τ_Y is the apparent yield stress, and η_P is, for historical reasons, called the “plastic” viscosity.

Casson bodies

The Casson body model^[24] is a semiempirical model used to describe shear thinning behavior after an apparent yield stress has been exceeded. It is, in fact, a combination of the apparent yield stress with the power law model, whereby

the power law index n is arbitrarily set to 0.5:

$$\tau^{0.5} = \tau_Y^{0.5} + k_2 \dot{\gamma}^{0.5} \quad (11)$$

An example of such a flow curve is presented in Fig. 6c, and viscosity as a function of shear strain rate is depicted in Fig. 7c. Many pharmaceutical ointments and creams show a similar shape of the flow curve with an extended upper Newtonian region. In these cases, an extrapolation of the linear portion of the flow curve to zero shear strain rate in order to obtain a “dynamic yield stress” is often utilized.^[25]

A more general mathematical description of shear thinning materials comprising an apparent yield stress is given by the Herschel–Bulkley model:^[26]

$$\tau = \tau_Y + k_2 \dot{\gamma}^n \quad (12)$$

which again is a simple extension of the power law model. For $n = 1$ Eq. 12 reduces to Eq. 10. Hence, power law and Bingham model are two extremes of the Herschel–Bulkley model.

Influence Factors on the Viscosity

Pressure

The viscosity of Newtonian and non-Newtonian materials increases exponentially with an increase in pressure. However, these changes are extremely small, and under atmospheric conditions of ± 1 bar, they are hardly detectable. Hence, the pressure is normally not controlled during rheological measurements. In some circumstances, the pressure exerted on, for example, oils and lubricants, can take up values in excess of 1 GPa (oil rigs, lubricants in gears), and the increase in viscosity is substantial. In such applications, it is thus required to consider the pressure as a factor when studying their rheological properties.

Temperature

An increase in temperature is accompanied by a decrease in viscosity. For Newtonian materials, this relationship can be approximated to the Arrhenius equation. To obtain an accuracy of $\pm 1\%$ in the measurements of the viscosity of water requires a temperature control of $\pm 0.3^\circ\text{C}$.^[1] The temperature dependence increases with an increase in viscosity. Thus, the demands on temperature control are even higher for more viscous materials. The shearing of the samples itself also generates heat. To ensure that the heat is not effective in altering the

temperature of the sample and equipment, the heat has to be removed quickly.

Shear time

Pharmaceutical preparations often provide lyogels with a colloid-like structure. For example, polymers with unbranched linear structures form matrices with parallel arrangement of individual chains. The van der Waals interactions between these chains lead to a higher degree of order. Areas of high order are separated from each other by amorphous areas. Laminar or sphero-colloidal matrices are formed, for example, from Bentonite and colloidal silicon dioxide, respectively. In all these cases, the flow elements will not be able to adapt to an applied stress instantaneously, and shear thinning will hence result. At the end of shear, the original structure may be completely destroyed. At rest, Brownian motion will lead to a rebuilding of the inner structure in many cases, but in some instances, the rheodestruction process is irreversible. The observation of a gradual decrease in viscosity with shear followed by a gradual recovery of the original structure is called “thixotropy” and is usually related to shear thinning materials. For shear thickening samples, a similar hysteresis can be observed in some instances, which are referred to as “negative thixotropy” or “antithixotropy.” An example of negative thixotropy is polyethylene glycol containing semisolid formulations.

Thixotropic behavior can be detected in two different ways. In the “step test” the material is sheared initially at a constant high shear strain rate, which is, after a defined time span has elapsed, reduced to a very small value. The shear stress recorded during the high shear phase decreases in a shear thinning fashion, indicating structural breakdown. The inner structure is rebuilt during the low shear period and results in a gradual increase of the shear stress recorded. Alternatively, the “loop test” can be employed. Typical flow curves obtained from loop tests on thixotropic and negative thixotropic materials are illustrated in Fig. 8. If highly elastic colloidal matrices are subjected to step or loop tests, viscoelastic contributions to the changes in stress have to be taken into account.^[10]

LINEAR VISCOELASTICITY

Definition of Viscoelasticity

The particular response of a sample to applied stress or shear strain rate depends on the time scale of the experiment. If the shear strain rate is kept low, many materials appear to behave viscous, whereas at high shear

Fig. 8 Typical flow curves for thixotropic and negative thixotropic materials as obtained in a loop test.

strain rates, materials might behave rather elastically. The simultaneous existence of viscous and elastic properties in a material is called viscoelasticity, and one can assume that all real materials are viscoelastic in nature.

One very impressive example of a viscoelastic material is Silly Putty® (“bouncy putty”), which is a silicon-based polymer. If dropped onto a surface, it bounces back higher than a rubber ball, yet under light pressure, the material can be flattened with ease and remains in its new shape. If placed on the edge of, for example, a table, the material will slowly creep over the edge like liquid due to the influence of the force of gravity. Most working materials, however, do not behave in these extremes.

Linear and Nonlinear Viscoelastic Behavior

Materials can show linear and nonlinear viscoelastic behavior. If the response of the sample (e.g., shear strain rate) is proportional to the strength of the defined signal (e.g., shear stress), i.e., if the superposition principle applies, then the measurements were undertaken in the linear viscoelastic range. For example, the increase in shear stress by a factor of two will double the shear strain rate. All differential equations (see, for example, Eq. 13) are linear. The constants in these equations, such as viscosity or modulus of rigidity, will not change when the experimental parameters are varied. As a consequence, the range in which the experimental variables can be modified is usually quite small. It is important that the experimenter checks that the test variables indeed lie in the linear viscoelastic region. If this is achieved, the quality control of materials on the basis of viscoelastic properties is much more reproducible than the use of simple viscosity measurements. Nonlinear viscoelasticity experiments are

more difficult to model and hence rarely used compared to linear viscoelasticity models.

Mechanical Modeling

A general differential equation for linear viscoelasticity is:^[1]

$$\left(1 + \alpha_1 \frac{\partial}{\partial t} + \alpha_2 \frac{\partial^2}{\partial t^2} + \cdots + \alpha_n \frac{\partial^n}{\partial t^n}\right) \tau = \left(\beta_0 + \beta_1 \frac{\partial}{\partial t} + \beta_2 \frac{\partial^2}{\partial t^2} + \cdots + \beta_m \frac{\partial^m}{\partial t^m}\right) \gamma \quad (13)$$

where α_i ($i = 1, n$) and β_j ($j = 0, m$) are the constants, and τ and γ the shear stress and shear strain, respectively.

In order to derive some simple linear viscoelastic models, it is necessary to introduce the mechanical equivalents for a Newtonian and a Hookean body. First, it is assumed that β_0 is the only nonzero constant in Eq. 13:

$$\tau = \beta_0 \gamma \quad (14)$$

This equation describes Hookean elasticity, and $\beta_0 = G$ (G is the modulus of rigidity). In Fig. 9, the classical mechanical spring model representing Eq. 14 is illustrated. If, however, it is assumed that β_1 is the only nonzero constant in Eq. 13, then:

Fig. 9 Steel spring as the mechanical model for an ideal Hookean body: the length of the spring increases proportionally to the force applied, which is here represented by a weight that stretches the spring.

Fig. 10 Dashpot as the mechanical model of an ideal viscous material: the dashpot flows to similar extent but in a different time span depending on the force applied.

$$\tau = \beta_1 \frac{\partial \gamma}{\partial t} = \beta_1 \dot{\gamma} \quad (15)$$

The value of β_1 is equal to the viscosity η , and Eq. 15 thus describes the Newtonian body. The mechanical model of a Newtonian body is the “dashpot,” which is illustrated in Fig. 10. The rate of extension of the dashpot depends on the stress exerted, and if the dashpot becomes stress free at any time, it will remain in its current state of extension.

If it is now assumed that all constants except $\beta_0 (= G)$ and $\beta_1 (= \eta)$ are zero, the so-called Kelvin model results:

Fig. 11 Kelvin model: spring and dashpot are combined parallel.

$$\tau = G\gamma + \eta\dot{\gamma} \quad (16)$$

In mechanical terms, the Kelvin model is a parallel combination of a dashpot and a spring as illustrated in Fig. 11. The extension of dashpot and spring is always equal, as is the induced strain in both elements. If suddenly a shear stress is applied, the dashpot can only respond slowly but continuously. The response of the spring is hence inhibited, and its maximum elongation is only reached with delay. The viscosity of the dashpot determines the response time, i.e., the higher the viscosity, the slower the response of the system. When the application of the stress is terminated, the spring will try to contract to get back to its original state. Depending on the viscosity of the dashpot, this process is again more or less delayed.

The numerical description of the growth of strain in the Kelvin body is:^[1]

$$\gamma = \frac{\tau}{G} [1 - \exp^{-t/t_k}] \quad (17)$$

where t is the time and t_k the retardation time ($t_k = \eta/G$).

If all constants except α_1 and β_1 in Eq. 13 are set to zero, the following equation results:

$$\tau + \alpha_1 \dot{\tau} = \beta_1 \dot{\gamma} \quad (18)$$

Replacing α_1 with a time constant t_M ($t_M = \eta/G$; “relaxation time”) and β_1 as before with η leads to the so-called Maxwell model, which is depicted in Fig. 12. The Maxwell model comprises a serial connection of dashpot and spring, which respond to the stress with different velocities.

The stress growth for the model is described by:

$$\tau = \eta\dot{\gamma}[1 - \exp^{-t/t_M}] \quad (19)$$

Fig. 12 Maxwell model: spring and dashpot are combined in series.

The stress decline after the removal of the employed shear strain rate is modeled as:

$$\tau = \eta \dot{\gamma} \exp^{-t/t_M} \quad (20)$$

Pharmaceutical materials are rarely described by simple mechanical equivalents such as the Kelvin (solid-like behavior) or the Maxwell (liquid-like behavior) model.

Combinations of Kelvin and Maxwell units with different characteristic time constants (t_k or t_M) are usually required. Although models using Maxwell or Kelvin units have been reported,^[27,28] it is numerically sufficient to combine either Maxwell or Kelvin units into line spectra.^[29,30] Such line spectra are easier to handle, but require care in the choice of the properties of each individual element. If the experimenter cannot relate the elements chosen to structural features in the sample, such modeling is of little value. Examples of appropriate use of line spectra can be found in the literature.^[31,32]

Creep Experiments

In practice, viscoelastic properties can be determined by static and dynamic tests. The typical static test procedure is the “creep test.” Here, a constant shear stress is applied to the sample over a defined length of time and then removed. The shear strain is monitored as a function of time. The level of stress employed should be high enough to cause sample deformation, but should not result in the destruction of any internal structure present. A typical creep curve is illustrated in Fig. 13a, together with the four-element mechanical model that can be used to explain the observations. The creep compliance represents the ratio between shear strain rate and constant stress at any time t .

When the stress is first applied to the sample, the creep compliance rises from zero to a defined value instantaneously (A–B in Fig. 13a). One can assume that this is reflected in an extension of spring 1 (Fig. 13b). Primary structural units are stretched elastically. If the stress were removed at this point, the sample would recover completely. The value of the creep compliance at point B is called the instantaneous compliance:

$$J_0 = \frac{1}{E_0} = \frac{\gamma_0(t)}{\tau} \quad (21)$$

with E_0 being the instantaneous elastic modulus and $\gamma_0(t)$ the instantaneous strain for $\lim_{t \rightarrow 0} t = 0$.

If shear continued, more links between the structural units would break and re-form, but as weaker links do so at smaller time points, there is some retardation of this process. In Fig. 13a, this phase, which is called the retarded elastic region, is presented by the curved

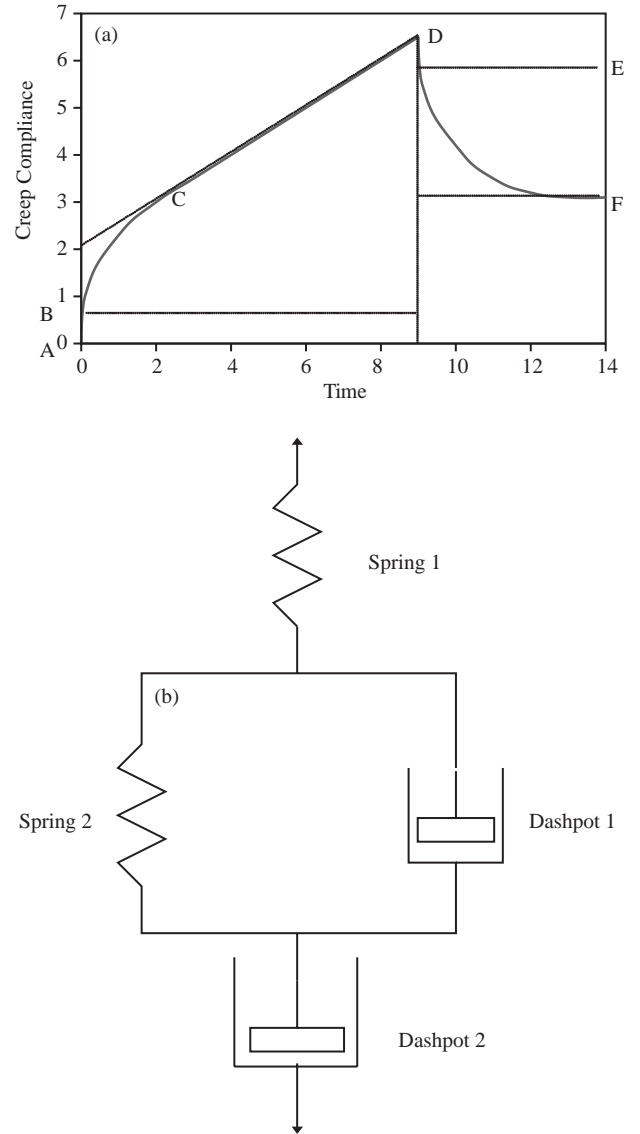

Fig. 13 (a) Typical creep curve: refer to the text for details. (b) Mechanical model to describe a typical creep curve.

compliance–time profile between the points B and C. In the mechanical model (Fig. 13b), this region corresponds to a slow movement of spring 2 and dashpot 1, i.e., the Kelvin unit. The value of the retarded compliance can be obtained from:

$$J_R = J_M [1 - \exp^{-t/t_m}] = \frac{\gamma_R(t)}{\tau} \quad (22)$$

with

$$t_m = J_M \eta_M = \frac{\eta_M}{E_R} \quad (23)$$

and J_M being the mean compliance, $\gamma_R(t)$ the retardation strain, t_m the mean retardation time, η_M the mean viscosity in the retarded phase, and E_R the retarded elasticity.

Finally, the material will flow as if it were a Newtonian body (C–D in Fig. 13a). Here, the ruptured links have no time to reform, and the linearity of this part of the curve indicates fully viscous behavior. In the mechanical model, this region refers to the deformation of dashpot 2 (Fig. 13b). The Newtonian compliance can be calculated from:

$$J_N = \frac{t}{\eta_N} = \frac{\gamma_N(t)}{\tau} \quad (24)$$

where η_N is the Newtonian viscosity, and $\gamma_N(t)$ is the Newtonian strain.

After the stress has been removed (point D in Fig. 13a), the recovery phase follows a pattern mirroring the creep compliance curve to some degree: First, there is some instantaneous elastic recovery (D–E; return of spring 1 into its original shape; see Fig. 13a, b). Second, there is a retarded elastic recovery phase (E–F; slow movement of the Kelvin unit into its original state; see Fig. 13a, b). However, during the Newtonian phase, links between the individual structural elements had been destroyed, and viscous deformation is nonrecoverable. Hence, some deformation of the sample will remain; this is in the mechanical model reflected in dashpot 2, which remains extended (Fig. 13b).

Oscillation

The most popular dynamic test procedure for viscoelastic behavior is the application of an oscillatory stress of small amplitude. This shear stress applied produces a corresponding strain in the material. If the material were an ideal Hookean body, the shear stress and shear strain rate waves would be in phase (Fig. 14a), whereas for an ideal Newtonian sample, there would be a phase shift of 90° (Fig. 14b), because for Newtonian bodies the shear strain is at a maximum, when a maximum of stress is present. The shear strain, when assuming an oscillating sine function, is at a maximum in the middle of the slope, because there is the steepest increase in shear strain due to the change in direction. For a typical viscoelastic material, the phase shift will have a value between $> 0^\circ$ and $< 90^\circ$ (Fig. 14c).

The shear stress applied:

$$\tau = \tau_0 \cos \omega t \quad (25)$$

hence produces a strain of:

$$\gamma = \gamma_0 \cos(\omega t - \delta) \quad (26)$$

Fig. 14 Oscillating shear stress and resulting shear strain: Hookean body (a); Newtonian body (b); viscoelastic material (c).

where τ_0 and γ_0 are the stress and strain amplitudes, respectively, ω is the oscillation frequency, and δ is the phase lag (“phase angle,” “loss angle”), which quantifies

the advance of the oscillatory stress to the oscillatory strain. The values for δ and the amplitude ratio γ_0/τ_0 depend on the material. In the linear viscoelastic range, these are material properties, although both vary with the frequency employed.

Eq. 26 can be rewritten as:

$$\gamma = \gamma_0 \cos \delta \cos \omega t + \gamma_0 \sin \delta \sin \omega t \quad (27)$$

where the term $\gamma_0 \cos \delta$ accounts for the amplitude of the component of strain in phase with the stress, and the term $\gamma_0 \sin \delta$ quantifies the amplitude of the component of strain 90° out of phase.^[10] From these terms, the storage (J') and the loss compliance (J'') can be defined by normalizing with the stress amplitude:

$$J' = \frac{\gamma_0 \cos \delta}{\tau_0} \quad (28)$$

$$J'' = \frac{\gamma_0 \sin \delta}{\tau_0} \quad (29)$$

This simplifies Eq. 27 to:

$$\gamma = \tau_0(J' \cos \omega t + J'' \sin \omega t) \quad (30)$$

In the case of an ideal Hookean body with $\delta = 0^\circ$, the loss compliance is zero and J' relates to the elastic energy, which has been stored in the material. No energy has been lost. Similarly, for a Newtonian body $\delta = 90^\circ$, while the storage compliance is zero. Here, the value of J'' is related to the rate with which energy was dissipated. In a viscoelastic material the values of J' and J'' are not equal to zero, and the relative proportion is quantified by:

$$\tan \delta = \frac{J''}{J'} \quad (31)$$

When controlling the strain applied rather than the stress, a similar analysis can be undertaken to derive the storage modulus G' and the loss modulus G'' , assuming that $\tau = \tau_0 \cos(\omega t + \delta)$ and $\gamma = \gamma_0 \cos \omega t$, instead of using Eqs. 25 and 26. Such analysis shows that:

$$\tau = \gamma_0(G' \cos \omega t - G'' \sin \omega t) = G' \gamma + \frac{G''}{\omega} \dot{\gamma} \quad (32)$$

with $G' = \tau_0 \cos \delta / \gamma_0$ and $G'' = \tau_0 \sin \delta / \gamma_0$. Again, the storage modulus G' describes the elasticity of the material and has a value of unity, if the body behaves fully elastically or is highly structured such as a gel. If G' is zero, then the body behaves as fully viscous and has no inner structure (e.g., a sol). The loss modulus refers to the

viscous properties and quantifies the degree of energy dissipation due to viscous flow. G'' is zero, if the body behaves Hookean. As before, the proportion between viscous and elastic behavior at a given frequency is described by $\tan \delta = G''/G'$.

The quantities of J' , J'' , G' and G'' are related via:^[10]

$$\tan \delta = \frac{J''}{J'} = \frac{G''}{G'} \quad (33)$$

$$J' = \frac{G'}{G'^2 + G''^2} \quad (34)$$

$$J'' = \frac{G''}{G'^2 + G''^2} \quad (35)$$

$$G' = \frac{J'}{J'^2 + J''^2} \quad (36)$$

$$G'' = \frac{J''}{J'^2 + J''^2} \quad (37)$$

Finally, one can consider the strain rate amplitude ($\dot{\gamma}_0$) instead of stress or strain, which results in:

$$\tau = \dot{\gamma}_0(-\eta' \sin \omega t + \eta'' \cos \omega t) \quad (38)$$

where $\eta' = \tau_0 \sin \delta / \dot{\gamma}_0$ is called the dynamic viscosity, and $\eta'' = \tau_0 \cos \delta / \dot{\gamma}_0$ is an unnamed parameter related to the storage modulus via:^[11]

$$G' = \eta'' \omega \quad (39)$$

The loss modulus is related to the dynamic viscosity accordingly, i.e.,

$$G'' = \eta' \omega \quad (40)$$

Typically, a spectrum of either pair of quantities as a function of frequency is reported, whereby the frequency normally covers values between 1000 Hz and 0.001 Hz.^[1] The changes in the parameters measured are utilized to describe the viscoelasticity of the material.

RHEOLOGICAL MEASURING TECHNIQUES

Classification of Rheometers

There are a vast number of rheometers available from a series of manufacturers, and Whorlow^[10] classified these into “steady rotating instruments” and “tube and slit rheometers.” Walters^[33] wrote a detailed account on the

fundamentals of the design of rheometers, and Ferry^[34] reviewed the instrumental techniques available for the investigation of viscoelastic properties. Special requirements and techniques available for the industry were analyzed by Sherman.^[35]

Physical Principles

The main requirement for exact and reproducible results is that the sample undergoes laminar flow during testing. Laminar flow appears as streamlined with a velocity profile of parabolic shape when monitored in a tube viscometer. For a Newtonian sample, shear stress and shear strain rate are at a maximum in close proximity to the walls of the test tube, and zero in the center. Shear thinning samples show truncated flow patterns, and the tendency to “plug flow” increases with a decrease in the power law index.^[1] In rotational viscometers laminar flow is the movement of the sample in concentric circles around the axis of rotation of the instrument.

Departures from laminar flow, which are attributed to inertia and/or viscoelasticity,^[11] result in turbulences, i.e., an uneven flow pattern with locally clear deviations from the flow direction. In the extreme, the flowing sample can start to circulate locally, which is known as “Taylor vortices” and mainly observed in concentric cylinder instruments, where the inner cylinder rotates,^[10] i.e., in “cup and bob viscometers.”

Reynolds number Re , which describes the ratio between inertial and viscous forces, can be used to determine whether the flow in tubes is laminar or turbulent:

$$Re = \frac{\rho d v}{\eta} \quad (41)$$

where ρ is the density of the sample, d is the diameter of the tube, v is the mean flow rate, and η is the dynamic viscosity of the sample. For rotating viscometers, Reynolds number combines the relevant parameters such as cylinder, cone, or plate radii with the physical properties of the material and the flow velocity. As these equations are very equipment specific, special literature should be consulted.

Other errors, which could influence the results obtained, are, for example, wall effects (“slipping”), the dissipation of heat, and the increase in temperature due to shear. In a tube, the viscosity of a flowing medium is less near the tube walls compared to the center. This is due to the occurrence of shear stress and wall friction and has to be minimized by the correct choice of the tube diameter. In most cases, an increase in tube diameter reduces the influence of wall slip on the flow rate measured, but for Newtonian materials of low viscosity, a large tube diameter

could be the cause of turbulent flow.^[10] When investigating suspensions with tube viscometers, constrictions can lead to inhomogeneous particle distributions and blockage. Due to the influence of temperature on viscosity (see “Influence Factors on the Viscosity”), heat dissipated must be removed instantaneously, and temperature increase due to shear must be prevented under all circumstances. This is mainly a constructional problem of rheometers. Technically, the problem is easier to control in tube rheometers than in rotating instruments, in particular, the concentric cylinder viscometers.^[1]

Steady Rotating Instruments

Concentric cylinder viscometers

The schematic principle of a simple arrangement, i.e., the “cup and bob viscometer,” is shown in Fig. 15. The driveshaft rotates with a given number of rotations per minute. If there were no friction between the two

Fig. 15 Cup and bob viscometer: r_1 = radius of the outer cylinder, h = length of the inner cylinder immersed in the liquid.

concentric cylinders, the spring would transfer the rotation completely. However, the material to be investigated, which fills the gap between the two concentric cylinders, is viscous and causes resistance against the rotation. As a result, the spring cannot follow the rotation of the drive shaft and gets twisted. Thus, a torque is produced, which is proportional to the shear stress applied.

For equipment with a narrow gap width between inner and outer cylinder, i.e., a ratio of greater than 0.97 for inner (r_1) to outer (r_0) cylinder, the shear strain rate equals:

$$\dot{\gamma} = \frac{r_0 \omega}{r_0 - r_1} \quad (42)$$

where ω is the angular velocity of the inner (rotating) cylinder. The shear stress in the sample depends on the couple C and the immersed length of the inner cylinder (see Fig. 15):

$$\tau = \frac{C}{2\pi r_0^2 h} \quad (43)$$

Combining Eqs. 42 and 43, the viscosity can be calculated from:

$$\eta = \frac{C(r_0 - r_1)}{2\pi r_0^3 \omega h} \quad (44)$$

A narrow gap between the two cylinders is problematic with respect to the alignment, which must be perfectly parallel, and the use of suspensions with larger particle size.^[1] Hence, commercial equipment often provides an alternative assembly with a wider gap. Corrections are required here to allow for the shear strain rate gradient in the gap, i.e., as the shear stress is larger in close proximity to the wall of the rotating cylinder, the shear strain rate will vary accordingly. For such assemblies, Krieger and Mason provided corrections allowing the calculation of the shear strain rate, shear stress, and viscosity at the inner cylinder:

$$\dot{\gamma} = \frac{2\omega}{n[1 - (r_1/r_0)^{2/n}]} \quad (45)$$

$$\tau = \frac{C}{2\pi r_1^2 h} \quad (46)$$

$$\eta = \frac{Cn[1 - (r_1/r_0)^{2/n}]}{4\pi r_1^2 h \omega} \quad (47)$$

where n is the power law index. The latter can be determined from a double-logarithmic graph of $C = f(\omega)$.

^aSee "Extrusion and Extruders."

End effects can lead to an overestimation of the shear stress applied, and one method of reducing such errors on the measurements involves the entrapment of an air bubble beneath the inner cylinder (see Fig. 15). The method, although popular, cannot completely eliminate frictional end effects,^[37] and hence an additional calibration should be performed. The viscosity of known Newtonian samples is utilized to calculate the theoretical angular velocity for that material from Eq. 44. The difference between the experimental and theoretical angular velocity as a function of viscosity renders a straight line, from which a correction factor can be obtained.

Parallel plate systems

Parallel plate systems consist of a stationary and a rotating plate, and the sample is sheared between them (Fig. 16). The volume of the enclosed sample is equal to:

$$V = \pi R_{pp}^2 H \quad (48)$$

where R_{pp} is the radius of the parallel plates, and H the gap width (see Fig. 16).

The shear strain rate at a given radius r is:

$$\dot{\gamma} = \frac{\omega r}{H} \quad (49)$$

and hence, the shear strain rate increases from the center of the plates toward the periphery, where it reaches its maximum value. The maximum shear stress, which occurs

Fig. 16 Parallel plate system: r = distance of a point from the center of the plates, R_{pp} = radius of the plates, H = gap between the plates, T = torque produced, ω = angular velocity of the rotating plate.

at the periphery, equals:

$$\tau_{\max} = \frac{2C}{\pi R_{pp}^2} \left(\frac{3}{4} + 0.25 \frac{\ln C}{\ln \dot{\gamma}_{\max}} \right) \quad (50)$$

The viscosity of the sample at the periphery of the plates is then calculated from:^[33]

$$\eta = \frac{3CH}{2\pi R_{pp}^4 \omega} \left(1 + \frac{1}{3} \frac{d \ln C}{d \ln \omega} \right) \quad (51)$$

However, the use of the parallel plate geometry is not recommended for viscosity measurements, because the shear strain rate variation along the gap between the plates is larger than that experienced in concentric cylinder systems.^[10] However, there might be advantages when using the geometry in oscillatory studies.^[1]

Cone and plate viscometers

A cone and plate geometry is illustrated in Fig. 17. The plate remains stationary, while the cone rotates, or vice versa. The angle between the cone and plate surfaces is usually less than 5°. For larger angles, the analysis of the results obtained from non-Newtonian materials would be complex or even impossible. For the small angles, sample ejection is less pronounced and temperature control can be easily achieved.^[10]

At a small enough gap the shear strain rate at any point in the gap is constant. Sample volumes can be kept small and the results are highly reproducible. However, the tip of the cone should just be in contact with the plate without exertion of a force. If there were a gap between the tip and

the plate, erroneous shear strain rates would be obtained. To avoid damage of the cone tip and plate midpoint, the tip might be truncated, yet the adjustment of the gap between the truncated end of the cone and the plate still has to be very precise. Truncation facilitates a more even sample distribution throughout the gap, and specially angled plate designs can prevent sample ejection and particle movement in suspensions due to centrifugal forces.

The shear strain rate at any point r in the gap between cone and plate is given by:

$$\dot{\gamma} = \frac{\omega r}{d(r)} = \frac{\omega}{\tan \theta} \quad (52)$$

where $d(r)$ is the distance between plate and cone surface at the point r , and $r = R$ for $d(r) = d$ at the perimeter of the geometry.

The shear stress can be obtained from:

$$\tau = \frac{3C}{2\pi R^3} \quad (53)$$

where R is the radius of the cone. Finally, the viscosity of the sample can be calculated from:

$$\eta = \frac{3C \tan \theta}{2\pi R^3 \omega} \quad (54)$$

These equations are still valid with an error sufficiently less than 1%, if the radius of the truncated tip of the cone, R_1 , is less than $0.2R$.^[10]

Tube and Slit Rheometers

Hydrostatic head viscometers ("capillary viscometers")

Hydrostatic head viscometers are capillary viscometers in which a hydrostatic head of fluid provides the driving pressure for the test material to flow through a capillary. Typically, these viscometers are used with Newtonian liquids or liquid-like samples. The simplest hydrostatic head viscometer is the U-tube of Ostwald. It consists of two bulbs of similar radius, linked by a capillary. A more advanced apparatus is the suspended level viscometer of Ubbelohde. Here, the additional bulb directly below the capillary ensures that there is the same pressure over the full length of the capillary. Both the Ostwald and the Ubbelohde viscometers are filled with the sample and suspended in a water bath to equilibrate the equipment and material at a given test temperature. The time for the sample to flow through the capillary, which is proportional to the kinematic viscosity of the material, is then measured.

Fig. 17 Cone and plate geometry: R = radius of the cone and plate, d = gap between cone and plate at the perimeter of the geometry, ω = angular velocity of the rotating cone, T = torque produced.

The pressure gradient along the capillary of an Ostwald viscometer is given by the Hagen–Poiseuille law:

$$\frac{dP}{dl} = \frac{8(dV/dt)\eta}{\pi r^4} \quad (55)$$

where dV/dt is the volume flow rate, i.e., the liquid volume passing the capillary in a defined time span, and r is the capillary radius. The shear stress τ in the liquid varies between $(r/2)(dP/dl)$ at the capillary wall and zero in the middle of the capillary, while the shear strain rate varies between $4(dV/dt)/(\pi r^3)$ and zero.^[1]

Special developments of capillary viscometers to be used with non-Newtonian liquids are available.^[1,10] However, these require that the sample does not show any thixotropy or negative thixotropy.

Slit viscometers

Flow between two parallel stationary walls as a result of an applied pressure gradient is known as slit flow. It can be considered as the two-dimensional analog of capillary flow. This technique is used when studying practical industrial processes such as injection molding of plastics, for example, for bottle-pack lines. The shear stress is here calculated from:

$$\tau = \frac{h}{2} \frac{dP}{dl} \quad (56)$$

where h is the slit height, and the shear strain rate is given by:^[1]

$$\dot{\gamma} = \frac{2(dV/dl)}{bh^2} \left(2 + \frac{d \ln(dV/dl)}{d \ln \tau} \right) \quad (57)$$

where b is the slit width.

Falling ball viscometers

The falling ball viscometer consists of a wider tube containing the test sample. The viscosity of Newtonian-behaving materials is obtained by measuring the time for a ball of known density and size to fall through the sample. The resistance of the liquid against the fall of the ball (w) is:

$$w = 6\pi r \eta v \quad (58)$$

and the force exerted on the ball due to gravity (F_B) is:

$$F_B = \frac{4}{3} \pi r^3 (\rho_B - \rho_N) g \quad (59)$$

Under equilibrium conditions, i.e., the ball is suspended by

the liquid and hence does not fall. Eqs. 58 and 59 are equal ($w = F_B$; $v = 0$). In Eqs. 58 and 59, r is the radius of the ball, v is the velocity of the falling ball, ρ_B and ρ_N are the densities of the ball and the Newtonian sample, respectively, and g is the gravitational constant (9.81 m sec^{-2}). Combining the two equations, the dynamic viscosity of the material can be calculated from:

$$\eta = \frac{2r^3(\rho_B - \rho_N)g}{9v} \quad (60)$$

The velocity of the falling ball is obtained by measuring the time the ball needs to fall a defined distance.

The falling ball can cause turbulent flow of the liquid that is replaced, and hence the velocity of fall should be kept low. The above equations also assume that the tube has an infinite diameter. However, as this is practically not the case, the viscosity obtained from Eq. 60 should be corrected for wall effects as follows:^[10]

$$\eta_{\text{corr}} = \eta \left(1 - 2.104 \frac{d}{D} + 2.09 \frac{d^3}{D^3} \right) \quad (61)$$

where d is the diameter of the falling ball, and D is the inner diameter of the tube. The Höppler-falling ball viscometer tries to reduce wall effects and turbulent flow by a nonvertical alignment of the tube.

Viscoelasticity Measurements

Creep tests can be performed with steady rotating viscometers. Conventional forced-oscillation measurements can also be performed with ordinary shear geometries such as plate–plate or plate–cone systems in rotating rheometers.

Wave propagation^[10,34,36] involves the generation of waves at the surface of the sample and the evaluation of the velocity and attenuation of these waves when traveling through the sample. “Steady-flow rheometers”^[37] produce a sample flow so that the velocity at a fixed point in the apparatus remains unchanged during the experiment. However, the individually flowing elements of the sample undergo an oscillatory shear, because the flow velocity varies from point to point in the equipment. In the Maxwell orthogonal rheometer, this is achieved with a plate–plate geometry. One of the plates rotates with a defined constant angular velocity, while the other plate is free to rotate and its velocity is usually close to that of the other plate.^[33]

RHEOLOGY OF PHARMACEUTICAL SYSTEMS

Liquid and Semisolid Dosage Forms

Rheological work on semisolid dosage forms such as ointments and creams has not been the main focus of research in recent years. Pharmacopoeias use viscosity measurements as a quality control parameter for liquids, which behave as Newtonian. The pharmacopoeial tests for non-Newtonian semisolid dosage forms are less concerned with rheological properties, and the use of penetrometer methods was preferred over true rheometry in some pharmacopoeias (e.g., DAB 10). The European Pharmacopoeia contains a monograph also describing the use of steady rotation instruments, but does not provide details for their use to characterize or classify samples. The simple approach of penetrometry and the unspecific employment of rheometers appear unjustified, if one considers the vast amount of literature from the 1960s and 1970s on ointment bases such as soft white paraffin,^[38–44] lanolin,^[45,46] and others,^[43,45,47] where rheological measurements were shown to be able to detect and explain among other things batch to batch and source to source variability of these materials. That the problems, which these materials can pose during manufacture, are still not resolved, is indicated by the occasional reoccurrence of rheological investigations, yet now combined with other modern analytical techniques^[48–50] such as low-frequency dielectric spectroscopy and thermoanalysis. Rheological investigations on gels, which are also important as semisolid dosage forms due to their gel–sol transition, have been reviewed extensively by Gallegos and Franco.^[51]

Suspensions

Suspensions are dispersions of solid particles in a liquid. The amount of solid material suspended occupies a certain fraction of space in the total volume of the suspension. This fraction is called the phase volume ϕ . Rheological observations on suspensions are all based on a volume solid per volume liquid basis, because the rheological behavior depends mainly on hydrodynamic forces, which act on the surface of the particles or particle aggregates, irrespective of the particle density.

For dilute suspensions (10% or less phase volume) of spherical particles in a Newtonian fluid, the Einstein equation^[52,53] can be used to predict the viscosity of the suspension, η , which also behaves as Newtonian:

$$\eta = \eta_L(1 + 2.5\phi) \quad (62)$$

where η_L is the viscosity of the suspending liquid. Eq. 62 does not consider interparticulate forces, particle size, or particle shape.

Flow of any concentrated suspension will become impossible when the solid particles can form a continuous three-dimensional network of contacts throughout the sample. This so-called maximum packing fraction ϕ_m depends mainly on the particle size distribution^[54] and the particle shape.^[55] Broader particle size distributions result in lower values of ϕ_m , because the smaller particles can fill the gaps between the bigger ones, and a deviation from spherical shape results in lower values of ϕ_m due to steric hindrance of packing.^[56] Also flocculation will result in a decrease in the value of ϕ_m , because the individual flocs are only loosely packed.

Concentrated suspensions can also behave as Newtonian, but more commonly these suspensions show shear thinning or shear thickening behavior.

For Newtonian flow, the viscosity of a concentrated suspension can be calculated from the Krieger–Dougherty equation:^[57]

$$\eta = \eta_L \left(1 - \frac{\phi}{\phi_m}\right)^{-\eta\phi_m} \quad (63)$$

Shear thinning of concentrated suspensions is typical for submicron particles dispersed in a low viscosity Newtonian fluid.^[58] At low shear strain rates, Brownian motion leads to a random distribution of the particles in the suspension, and particle collision will result in viscous behavior. At high shear strain rates, however, particles will arrange in layers, which can slide over each other in the direction of flow. This results in a reduced viscosity of the system in agreement with the principles of shear thinning. A pronounced apparent yield stress can be found for shear thinning suspensions, if the Brownian motion is suppressed by electrostatic repulsion forces, which result in three-dimensional crystal-like structures of the particles with low mobility.^[59]

Shear thickening will always follow at higher shear strain rates. This is mainly due to the breakdown of the particle layers mentioned before,^[58] or due to liquid film rupture between the particles and hence direct interparticulate contact.^[1] The latter appears to be more typical for suspensions with $\phi \geq 0.5$.

The rheology of pastes, which are highly concentrated suspensions, is very important for the process of extrusion and spheronization to produce pellets. This topic is covered by J.M. Newton elsewhere in this encyclopedia.^a

^aSee “Extrusion and Extruders.”

Emulsions, Microemulsions, and Liquid Crystals

Emulsions, microemulsions, and liquid crystalline systems are suspensions of deformable particles, and many of the principles stated earlier for suspensions are valid to a similar extent. The effect of the phase volume, however, is less pronounced.^[1]

Emulsions are increasingly non-Newtonian, i.e., shear thinning with increasing concentration of the lipophilic phase.^[1] The relative effects of droplet size and shape and their distributions are less well studied, compared to solid particle suspensions, but in general, an increase in viscosity is observed for smaller and more monosized droplets. Hence, an increase in energy input, for example, by homogenization, will always result in an increase in viscosity.

The viscosity of microemulsions has been studied several times in order to determine hydration and interactions between the dispersed droplets.^[60–64] It was found that an increase in hydration of the surfactant molecules resulted in rheological behavior more similar to that of suspensions containing solid particles in low concentrations. In any case, the microemulsions showed Newtonian flow characteristics.

Liquid crystals can be classified into lyotropic and thermotropic systems. The rheology of thermotropic liquid crystals is less documented, but in general, nematic liquid crystals were found to show Newtonian flow, whereas smectic and cholesteric liquid crystals demonstrated more or less pronounced plug flow.^[65] Plug flow is typical for non-Newtonian, shear thinning liquids.^[1]

The behavior of lyotropic crystals is usually non-Newtonian.^[66] Lamellar liquid crystals show thixotropic or negative thixotropic behavior,^[67] but shear thinning/thixotropy is more common.^[68–71] The shear thinning effect is ascribed to orientation of the liquid crystalline domains and some structural breakdown. Viscoelasticity has also been observed.^[72,73] If the concentration of the surfactant molecules is, however, low and close to the CMC, Newtonian flow will be observed.^[73]

Flow of hexagonal liquid crystalline systems is presumably a function of the alignment of the rod-like aggregates along their long axis in the direction of flow.^[74] The shear thinning flow process can be accompanied by an apparent yield stress.^[75] Viscoelastic behavior has also been reported.^[76]

Cubic liquid crystalline systems have been described as clear, stiff gels.^[77] As such, they show shear thinning after an apparent yield stress has been exceeded. The viscoelastic properties are also typical for the gel character: a broad

linear viscoelastic range and a frequency-independent elastic component, which is considerably higher than the viscous component, are observed.^[78,79]

Film Coatings

Rheological techniques such as creep tests or oscillation can be applied to film coatings in order to assess their viscoelastic properties. However, the tests are undertaken typically in tension, not in shear. A typical creep–time curve for polymer films can be divided into three parts.^[80] After an instantaneous initial strain has developed, polymer films will often undergo a period of transient response to the stress applied. The tensional strain rate decreases with time and reaches a minimum steady-state value. In the third stage, the creep rate increases again leading to final rupture of the film. In typical experiments, however, the recovery phase is initiated while the tensional strain rate value is still in the steady-state region. The decrease in the tensional strain rate during the transient stage is related to changes in the substructure of the film. These changes result in an overall increase in the resistance to dislocation motion. A constant tensional strain rate during the steady-state creep stage, however, is indicative for the substructures in the film to have stabilized, and that there is a dynamic balance between strain hardening and softening processes. Creep curves obtained on polymer films might not possess a transient or steady-state stage. In the former case, the creep curve is linear throughout, whereas in the latter case, the transient part of the creep curve ends in a linear part parallel to the time axis. If the creep–time curve is fully linear, steady flow will result in permanent deformation, whereas the occurrence of only a transient stage should result in complete recovery.

SURFACE RHEOLOGY

The measurement of rheological properties at the surface of a solution or the interface between a solution and, for example, a biological film is called surface or interfacial rheology. In this technique also, experiments are performed either in tension, compression or shear, and phenomena observed in bulk rheology such as flow and viscoelasticity are also observable. An introduction to the techniques available and some key findings are discussed by Warburton.^[81,82]

Roller Compaction Technology for the Pharmaceutical Industry

Ronald W. Miller

Bristol-Myers Squibb, Global Pharmaceutical Technologies, New Brunswick, New Jersey, U.S.A.

Paul J. Sheskey

The Dow Chemical Company, Midland, Michigan, U.S.A.

INTRODUCTION

The pharmaceutical industry uses granulation methods to enlarge and densify small powder particles into larger ones. This improves powder flow so that the material can be processed effectively and efficiently further into solid dosage forms. There are two pharmaceutical methods of granulation, wet and dry. Wet granulation methods are widely described in the literature; for example, *Encyclopedia of Pharmaceutical Technology (Granulations)* is solely devoted to this technology.^[1]

Dry granulation processing does not use moisture or heat to process powder into densified granules. In the pharmaceutical industry, there are two methods of dry granulation: slugging and roller compaction. Very little has been written about pharmaceutical dry granulation technology. Its contemporary use in the industry is about 50 yr–60 yr, beginning in the late 1940s. However, its popularity has risen in the last 20 years in parallel with the increased research for new efficacious active drug molecules in the pharmaceutical industry. These new active molecules cannot be processed so easily using wet and heat granulation processing steps, because of their chemical fragility and sensitivity. Therefore, this pushes the necessity for the use of dry granulation processing techniques to advance new sensitive active solid dosage forms in the 21st century.

BACKGROUND

Briefly, in dry pharmaceutical granulation processing, the powder particles are aggregated under high pressure, typically 30 bar–70 bar pressure. Particulate matter can be aggregated when compressed at high pressure because of bonding forces developed by the direct contact between the solid surfaces. The high pressure serves to improve the contact area between the surfaces and thus the overall bonding strength. Sometimes, a binding agent is needed to provide additional bonding strength. Later in the chapter, there is more about the kind of excipients used in roller

compaction formulations to aid the manufacturing of pharmaceutical products.

In the pharmaceutical industry, dry granulation processing in the 1950s–1970s favored a process called slugging. This process design consisted of feeding powder into a large compression machine, such as a Stokes D3 type compression machine, where the powder was compressed into large tablets or slugs, typically in the order of 1-in. diameter with a tablet gauge of about 0.25 in. The tablet slugs were subsequently milled by a separate sizing machine to an appropriate particle size distribution, and further processed into pharmaceutical capsules, powder for oral suspensions, sachets, or tablet dosage forms. The slugging process is still used today by only a few manufacturing firms that have old pharmaceutical or over-the-counter formulation processes. Today, modern pharmaceutical formulation processes introduced into the Americas, Western Europe, Australia, and parts of Asia do not use this kind of dry granulation equipment in newly developed formulations. The slugging machine process is a relic of the past in the 21st century of modern pharmaceutical technology; roller compaction is the key technology to dry granulation processing of the future.

Some characteristics are described briefly about the slugging process to complete the technology information for the reader. The slugging process is externally influenced by raw material feed properties such as powder cohesiveness, density, flow characteristics, and powder particle size distribution. The slugging machine's design characteristics such as machine type, feed hopper, feed frame, die diameter and tooling features, compression speed, and slugging pressure also influence the slugging process and the final product properties. In general, the key processing operational aspect of slugging is to maintain a uniform powder fill weight into the dies during the dynamics of the slugging process. This assures the best chance to manufacture uniform powder slugs and ultimately, uniform densified granules. The compression-slugging setup is a key essential to maximizing the slugging throughput and minimizing the hopper feed frame and die powder flow problems associated with the process. Slugging

**Table 1** Disadvantages of slugging

Single batch processing	Excessive air and sound pollution
Frequent maintenance change-overs	Increased use of storage containers
Poor process control	Increased needs of manufacturing space
Poor economies of scale	Increase of logistics
Low manufacturing throughput per hour	More energy and time required to produce 1 kg of slugs than 1 kg of roller compact

(Courtesy of Handbook of Pharmaceutical Granulation Technology.^[2])

compression is normally performed at 4 tn–6 tn hydraulic pressure, at a rate of 10–30 turret revolutions per minute. The specific machine tonnage, turret speed, and roll dwell time required for the process are dependent on the powder blend's physical properties, the tooling configuration, machine parts, and ultimately the slug specifications. Typical slugging machine output ranges from 30 kg hr⁻¹ to 50 kg hr⁻¹. Slugging machines are not instrumented with modern devices to control their performance. There are numerous disadvantages with the slugging technology in the pharmaceutical industry as listed in Table 1.

BENEFITS OF ROLLER COMPACTION

This chapter identifies key aspects of roller compaction technology. Unlike the slugging process technology, roller compaction technology is well suited for dry granulation agglomeration in the era of modern development of active pharmaceutical ingredients and the design of modern pharmaceutical plants. The increasing scale of manufacturing pharmaceutical products worldwide and the need for high processing rates, together with increased levels of good manufacturing practices necessitate controlled dry granulation processes with as few processing steps as possible. This has been accomplished by instrumenting roller compactors to automate and control the mechanical process. Roller compaction technology plays a very important role in providing competitive cost control, safety, and quality products in the pharmaceutical industry. Key roller compaction benefits observed in the pharmaceutical industry are identified in Table 2.

A number of these attributes, best technology practices and features, were rated for their industrial and pharmaceutical importance and reported by Miller and Sheskey in 2001.^[3] Ultimately, today's roller compaction technology offers a continuous process with better process controls, manufacturing efficiencies, and environmental protection than an archaic slugging process technology.

PREFACE: POWDER GRANULATION AND COMPACTION

Powder granulation is a process of powder size enlargement that incorporates small particles into larger ones. The definition of granulation comprises a range of different size enlargement methods that can be classified as either dry or wet. In wet methods, a suitable liquid is used to agglomerate the small powder particles into a mass. The wet mass is subsequently dried and sized for further down-stream processing needs. Wet granulation methods have been the most widely used powder granulation technology in the production of pharmaceutical products, particularly in modern pharmaceutical manufacturing.

The chief reasons to granulate powders for the manufacture of pharmaceutical dosage forms are described by Kristensen and Schaefer.^[1]

- To improve powder flow properties for dosage filling and compression processes.
- To eliminate wet granulation induced degradants and to improve product stability.
- To prevent active product ingredient from segregating.
- To reduce bulk volume thereby minimizing storage and enhancing transport.
- To reduce potential environmental and safety hazards

Kristensen and Schaefer provide ample literature references in their chapter in the Encyclopedia of Pharmaceutical Technology about granulation size enlargement methods.^[1] Capes,^[4,5] Pietsch,^[6,7] Sherrington and Oliver,^[8] Kapur.^[9] Others also referenced about wet granulation technologies: Kristensen and Schaefer,^[10] Lindberg,^[11] Fonner, Anderson, and Banker,^[12] Anderson, Banker, and Peck,^[13] and Ghebre-Sellassie.^[14]

COMPACTION THEORY

The bonding forces in a dry aggregate are important to granulation properties such as granule integrity, flowability, friability, density, compressibility, and size for down-stream manufacturing process steps.^[1] Rumpf and coworkers described the bonding mechanisms occurring during dry granulation as a mixture of van der Waals' forces, mechanical interlockings, and a recombination of bonds established between freshly created surfaces and solid bridges, created because of partial melting and solidification during compression.^[15]

A general theory describes particle bonding related to roller compaction in the *Handbook of Pharmaceutical Granulation Technology*.^[2] The process of dry granulation relies on interparticulate bond formation. Granule bond

Table 2 Advantages of roller compaction

Simplifies processing	Uses less raw materials
Eliminates aqueous and solvent granulating	Eliminates water-induced degradants
Facilitates powder flow	Improves process cycle time
Uses minimal energy to operate	Prevents particle segregation
Requires less man-hours to operate	Facilitates continuous manufacturing
Improves drug dosage weight control	Improves content uniformity
Reproduces consistent particle density	Does not require explosion-proof room or equipment
Produces good tablet and capsule disintegration	Produces a dry product that is process scaleable

(Courtesy of Handbook of Pharmaceutical Granulation Technology.^[2])

formation is characterized in different stages, which usually occur in the following order:

1. Particle rearrangement.
2. Particle deformation.
3. Particle fragmentation.
4. Particle bonding.

Particle rearrangement occurs initially as powder particles begin filling void spaces. Air begins to leave the powder blend's interstitial spaces, and particles begin to move closer together. This action increases the powder blend's density. Particle shape and size are key factors in the rearrangement process. Spherical particles will tend to move less than other-shaped particles because of their close initial packing to one another. Particle deformation occurs as compressional forces are increased. This deformation increases the points of contact between particles where bonding occurs and is described as plastic deformation.^[2]

Particle fragmentation follows as the next bonding stage. This occurs at increased compression force levels. At this stage, particle fracturing creates multiple new surface sites, additional contact points, and potential bonding sites. Particle bonding occurs when plastic deformation and fragmentation happen. It is generally accepted that bonding takes place at the molecular level, and this is due to the effect of van der Waals' forces.^[2]

When powder granules undergo an applied force or stress, a stress force is released from the granules. The granules attempt to return to their original shape or form; this is described as *elastic deformation*. A deformation, which does not totally recover after the stress is released, is a *plastic deformation*. Elastic and plastic deformations can occur simultaneously, but one effect usually predominates.

Parrot identified that three theories of compressional bonding exist: mechanical, intermolecular, and liquid-surface film. Mechanical bonding purports that individual particles undergo elastic, plastic, and brittle deformation. Bonding of this nature occurs because particle surfaces intertwine, forming mechanical bonds. Intermolecular

theory identifies that there are some unsatisfied surface ions that have a potential need to bond to one another. Under pressure, intermolecular forces become pushed together close enough so that van der Waals' forces can act to consolidate particles. The liquid-surface film theory identifies that bonding occurs because of the existence of a thin liquid film. The thin liquid film is generated from pressure induced by the energy of compression. This mechanism acts as a bonding agent promoting mechanical strength and an enlarged particle.^[16] Very little information has been written about this last theory.

Dehont et al. provided a simplified approach to roller compaction theory.^[17] They described that powder granules move through stages in the feed area. The material is drawn into the gap by rubbing against the roll surfaces. The densification that occurs in this area is particle rearrangement. At this stage, the speed of the powder is slower than the peripheral speed of the rollers. Fig. 1 represents compactor rolls in the horizontal plane; powder is pushed vertically downward into the compaction area.

Note in Fig. 1, α is the nip angle and β the material in volume space. The material is located in the compaction area between α and the horizontal axis (Fig. 1). At this stage, the material undergoes additional compaction

Fig. 1 Front view of compactor rolls in horizontal plane. (Courtesy of Ellis Horwood.^[17])

forces. The particles undergo plastic deformation and are bonded. Dehont's team noted that nip angle varies according to the material characteristics of particle size and density and the angle is about 12° .^[17] They defined the neutral angle, γ , which corresponds to the point where the pressure applied by the rollers is the greatest on the material. They also defined elastic deformation, δ , and that occurs after the compact begins leaving the compression roll area. Compacted flakes may increase in size due to material elastic deformation and actually may have a larger thickness than the roll gap, e .^[17]

Dehont et al. developed Eq. 1 for the linear variation of flake thickness at a specific roll diameter:^[17]

$$e_1 = D(d_0/d_1 - d_0)(1 - \cos \alpha) \quad (1)$$

where e_1 is the flake thickness, D , the roll diameter, d_0 , the material density at angle α , and d_1 , the flake density.

Dehont et al. assumed that the material in the compaction area remains horizontal and moves at the peripheral speed of the rollers. They also considered that the angle α is independent of the roller diameter size and noted that the flake thickness e_1 depends on the roller speed, the roller surface, and the compaction pressure. All these parameters influence the density of the flake, d_1 . Dehont et al. concluded that if the same flake thickness was obtained with different roller diameters, the flake density would be greater with larger diameter rollers.^[17] This is due to the greater nip angle formed, with the larger rolls allowing more material to be compacted.

Heckel considered the compaction of powders analogous to that of a first-order chemical reaction. The pores were the reactant and the densification of the material the product. The proportionality between the change of density with pressure and the pore fraction was the process kinetics.^[18] Heckel explained mathematical constants that described the compaction behavior of a given powder and developed a mathematical relationship, Eq. 2.^[18]

$$\ln(1/1 - D) = KP + \ln(1/1 - D_0) \quad (2)$$

where D is the relative powder density, D_0 , the relative loose powder density at zero pressure, P , the pressure applied, $1 - D$, the pore fraction, and K , the proportionality constant.

The expression of density–pressure relationship permitted the determination of density values in the range of the pressures investigated. Heckel described mathematically that the curved region when plotting $\ln(1/1 - D)$ vs. P is associated with powder densification.^[18] This occurred by a mechanism of individual particle movement in the absence of interparticle bonding. Heckel concluded that the densification represented by the linear region of the plot, $\ln(1/1 - D)$ vs. P , occurred by

plastic deformation of the compact after an appreciable amount of interparticle bonding had taken place. For quantitative reasons, Heckel redefined the mathematical expression denoting a constant, $A = \ln(1/1 - D_0)$, which is quantitatively valid except at low pressures. He postulated that the constant A , which is somewhat larger than $\ln(1/1 - D_0)$, represents the degree of packing achieved at low pressures as a result of rearrangement processes before appreciable amounts of interparticle bonding take place.^[18] He also postulated that the constant K , the slope of the linear region, gives a measure of the compact to densify by plastic deformation.

Heckel concluded that density–pressure data indicate the rate of the change of density with pressure, at any pressure, is proportional to the pore fraction in the compact at that pressure. Additionally, density–pressure curves may be described by two parameters. He theorized that one was related to low pressure densification by interparticle motion. The second measured the ability of the compact to densify by plastic deformation after appreciable interparticle bonding.

Johanson identified, through very comprehensive mathematical models and relationships, material properties, press dimensions, and operating conditions for roll compactors. For more information, the interested person should read the entire reference.^[19] In part, he described that roller compaction involves a continuous shear deformation of the granules into a solid mass.

To satisfy the theory's assumption, it was postulated that the material be isotropic, frictional, cohesive, and compressible. Fig. 2 depicts material in a press that undergoes shear deformation into a solid mass.^[19]

In Fig. 2, P_0 is the horizontal pressure between rolls, θ , the angular position of roll bite, α , the nip angle, $2d$, the

Fig. 2 Front view of compactor rolls in horizontal plane depicting powder regions under different compaction forces. (Courtesy of Transaction ASME.^[19])

roll diameter D , h , the height above the roll center line at which feed pressure P_o is applied, P_m , the horizontal pressure at $\theta = 0$, and S , the roll gap.

Johanson pointed out that no roller compactor theories at that time determined the angle of the nip and the bulk density at $\theta = \alpha$, except by actually rolling the granular solid in a roll press. He also provided a method to calculate the nip angle and the pressure distribution between the rolls. His calculations determined the pressure distribution above the nip area and the pressure in the nip area.^[19]

He provided the technical rationale to calculate the nip pressures in the nip region. He showed that material trapped in a volume V_α between arc-length segments ΔL must be compressed to volume V_θ between the same arc-length segments. The relationship requires that the bulk densities γ_α , γ_θ in volumes V_α , V_θ be related by Eq. 3 (Fig. 3):^[19]

$$\gamma_\alpha / \gamma_\theta = V_\theta / V_\alpha \quad (3)$$

Fig. 3 defines the following: P_o —horizontal pressure between rolls; θ —angular position of roll bite; α —nip angle; $2d$ —roll diameter D ; h —height above the roll center line at which feed pressure P_o is applied; P_m —horizontal pressure at $\theta = 0$; S —roll gap; ΔL —arc-length segments; V_α —material trapped in volume space described by arc-lengths; V_θ —compressed volume space described by arc-lengths; γ_α and γ_θ —respective powder bulk densities in volume spaces V_α and V_θ ; and K —a material property constant for a given moisture content, temperature, and time of compaction.

Johanson stated that the pressure σ_θ at any $\theta < \alpha$ can be determined as a function of the pressure σ_α , at $\theta = \alpha$, by the pressure–density relationship. It was understood that for increasing pressures, log density was a linear function of log pressure.^[20]

Fig. 3 Front view of compactor rolls in horizontal plane depicting nip angle. (Courtesy of Transaction ASME.^[19])

Johanson found that the nip angle does not depend on the magnitude of the roll force or the roll diameter. He demonstrated that the nip angle was affected very little by the geometry of the press or the cut grooves on the roll surface. It was mostly influenced by the nature of the materials that were compressed. The very compressible materials, with small K -values, had very large nip angles. On the other hand, incompressible materials, with large K -values, had very small nip angles. Ultimately, Johanson's results showed that material properties determine the maximum pressure that a roller press can apply to a material.

Parrott evaluated compaction of several pharmaceutical powders into compact sheets that were sized by an oscillating granulator into granules. He studied flake thickness, bulk and tap densities, angle of repose, and flow rate after sizing. His work demonstrated that one could improve most granule densities but not necessarily improve granule flow properties.^[21]

Nearly all particulate matter can be aggregated when compressed at high pressure. In some cases, pressure alone cannot achieve sufficient bonding strength, therefore, a binding agent is required to be added to the powder blend.^[1] Polymeric binders added to mixtures at certain percentages form highly viscous bridges between particle-to-particle powders. When the polymeric mixtures are compressed, they increase the overall compact strength and enhance particle-to-particle bonding and can improve powder flowability. Later, in this chapter, additional information about the use of binders will be discussed.

Pietsch described a compaction capacity throughput equation for a roller compactor using flat rolls. The equipment capacity equation is theoretical in nature; it assumes that all compacts are 100% useable for downstream processing needs. Compact capacity throughput, C_c , for a roller compactor can be determined by Eq. 4.^[6]

$$C_c = \pi D l h_A n 60 \gamma \quad (4)$$

where C_c is the roller compactor throughput (kg hr^{-1}), D , the roller diameter (cm), l , the roller length, working width (cm), h_A , the gap width between the rollers, sheet thickness (cm), n , the revolutions per minute (min^{-1}), and γ , the apparent sheet density (kg cm^{-3}).

DESIGN FEATURES OF ROLLER COMPACTORS

Certainly, a key enhancement that highlights today's pharmaceutical industry's state-of-the-art roller compactors, is programmable logic controllers (PLCs). They are used to control and monitor mechanical parts that regulate screw feed rate, roll speed, roll pressure, roll gap, vacuum deaeration, and mill speed. This section will not discuss

PLC designs as it relates to compactor design features and advancements.

Briefly, a key machine innovation, vacuum deaeration, was a new important feature design added by some roller compactor vendors in the early-mid-1990s. The design feature has been shown to help premodify raw material density prior to compacting and increase throughput.^[22] Other equipment features such as multiple horizontal or angled feed screws have assisted manufacturing a uniform raw material feed across the rolls.^[22,23] Newly designed roll machine blocks, featuring cantilever roll systems, offer more efficient ways to clean, handle, and facilitate product and equipment changeovers. New storage hoppers and various screw feeder designs have improved delivering poor flow powder to the rolls.

A history of hopper and feed screw designs showed that each design evolved to facilitate and improve powder flow

to the compactor feed screw conveyance system. Feed hopper designs depicted in Fig. 4 show designs incorporated in older compactor models [examples (a)–(c)]. Dehont et al. described the powder compaction feeding systems that were in use up to 1989.^[24]

Hopper (a) was used when the material had good rheological characteristics. Materials that had good but unique flows, and needed to be evenly distributed across the roll surface, such as granular salts, used hoppers that had guiding flaps (b). When the powder material had poor rheological characteristics, a vertical flap distribution box (c) was fitted under the hopper. It was primarily used when compacting ores. Force-feeder designs, examples (d)–(f), are more commonly used in the pharmaceutical industry. They are employed with various configured designs and shapes to supply poorly flowing powder to the nip roll region.

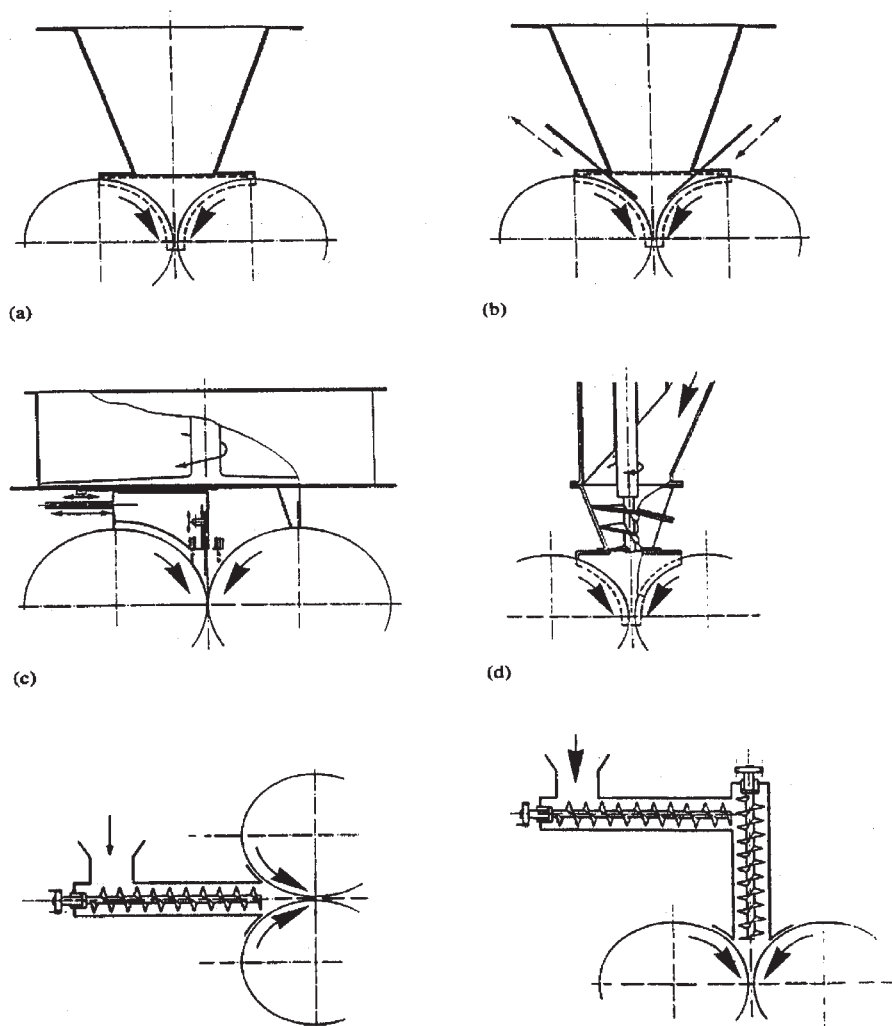

Fig. 4 Feed hopper designs: (a) simple hopper, (b) simple flap hopper, (c) flap distribution box, and (d) force-feeder. (Courtesy of Ellis Horwood Limited.^[17])

Pietsch described, in Fig. 5, modern feed screw system designs; (a) depicts vertical force-feeding screw with slightly tapered end, (b) an inclined feed screw, (c) a vertical tapered and blade angled feed screw, and (d) horizontal (single or dual) straight feeder screw(s).^[25]

Innovatively designed feed screw systems are used commercially in roller compactors worldwide. An example is shown in Fig. 6.

Sizing devices are now trimly fitted to the compactor body and controlled by variable speed drives. Most compactors no longer require a second machine (mill) in tandem to size compacts as required by slugging technology. Roller compactors have clean-in-place (CIP) systems that offer environmental and safety features. These systems minimize human exposure to chemicals and improve cleaning efficiencies, Fig. 7.

ROLL CONFIGURATION

Compactor design features have evolved over the years. By the mid-1970s, research revealed a number of roll design improvements that increased compacting efficiency. Three key conditions were identified, at that time, which optimized the roll compact throughput and minimized leakage of noncompacted powder.^[26]

- Adequate powder supply must enter the gripping zone.
- Powder must be conveyed fully into the narrowest part of the roller gap.
- Compaction pressure must be distributed as uniformly as possible across the whole roller-gripped powder mass.

Equipment engineers and researchers worked on improving feeding equipment systems and roll designs to satisfy and maximize the above conditions. Some of the key advances are identified in Ref. 22 and are re-emphasized in this chapter.

Because of powder feed variability at the nip and in the roll gap regions, powder leakage is produced during the compaction process. This situation produces excessive fines and possible undesirable processed material. Usually, this problem is caused by uneven powder flow and compact formed when the powder is fed towards the middle of the roll width. Granules produced under these conditions are typically not optimal for further pharmaceutical processing.

Trials performed by Funakoshi, Asogawa, and Satake using rectangular aperture chutes, fitted at the end of a feed screw, aided in preventing uneven powder flow across the roll width. Funakoshi's team demonstrated the positive effects of having concavo-convex roller pair fitted with inner ring walls. This feature counteracted side seal effects (fractured or incomplete compacted edges). They also designed and tested other rolls (concavo-convex with rim), which allowed the powder to distribute more uniformly

Fig. 7 Roller compactor CIP system. (Courtesy of Gerteis Co.)

across the roll width. This design reportedly minimized powder leakage during compaction.^[26]

Funakoshi's team also showed, when the roll rim inner angle is zero that the powder is not adequately and uniformly delivered to the gripping and compacting zones. This occurred because the stationary side seals acted as resistors to the powder flow.^[26] Their work demonstrated that the formed compact and the compaction pressure (using standard rolls) produced an uneven compact across the roller ends because of side seal friction. When they employed the newly designed concavo-convex rimmed rolls, it protected the compact from the adverse side seal fracturing effect. Funakoshi, Asogawa, and Satake also determined a proper selection of rimmed rollers, which delivered adequate powder to the compaction zone and also conveyed powder fully across the roller gap region. They concluded that the height and slope of the inner walls' rims optimally influenced the side seal effect. A 65° inner wall slope produced 2.5%–3.0% fines' leakage during the compaction of lactose. When the rolls had no inner wall rims, the fines' leakage was 15%. In summary, they optimized the compact and pressure distribution along the rolls by using the concavo-convex rimmed shaped rolls. They acknowledged that the best roll design was still dependent on the powder raw material properties.^[26]

Parrot further substantiated the usefulness of rimmed concavo-convex roller pair to increase the density of

several pharmaceutical powders. His work resulted in optimizing a process with an uncompacted leakage rate of 5%. The optimization depended on the physical properties of the powder and the machine operating conditions such as the roller gap, feed screw speed, and roll speed.^[27] Some of their key design feature findings are summarized:

- Installing concavo-convex roll surface rather than flat roller pair.
- Installing rectangular feed chute and flaps.
- Designing cylindrical, conical/cylindrical, or tapered-shaped variable speed auger feed screws.
- Optimizing roll rim angle to 65°.
- Installing digital and analog variable feed screw controllers.
- Developing horizontal and variable screw feed systems.

Jerome et al. in the 1980s studied the effects of compactor adjustments on powder blend properties. His team's research showed that pressure applied by the movable roller is not a predominant factor. They found that the most important variable was the compactor feed screw in relation to the roll speed. They correlated improved tablet compression hardness to the feed screw speed in relation to the speed of the rolls.^[28]

Typical compactor roll configurations are shown in Fig. 8. Most compactors now have one floating roll and

Fig. 8 Roll configuration designs. (Courtesy of Alexanderwerk Inc.)

one fixed roll each on separate bearing blocks. An illustration of this is shown in Fig. 9.

Currently, one manufacturer of roller compactor equipment for the pharmaceutical industry has a fixed roll-pair system. This type of roll design system relies on powder gravity feed and a specially designed compression feed screw to continuously deliver powder feed stock to the fixed roll pair, Fig. 10.

Pietsch described two pairs of rollers with different diameters D_1 and D_2 , with identical roll gaps h_A . He theorized that if the peripheral speed of both pairs of rollers is the same, roller compaction takes place more gradually in the case of the larger roll pair. At the same time, the larger diameter roll pair pulls a larger powder

volume into the nip region, resulting in a higher density of compacted product. The larger diameter roll pair also minimizes air entrainment more efficiently than the smaller diameter roll pair when both are operating at the same peripheral speed.^[25]

Pietsch noted that the peripheral roll speed and particulate powder speed are not equivalent in the entire compaction zone. Throughput does not increase proportionally with roll speed. There are two effects that hinder throughput: starved conditions in the feed zone, and secondly, too much squeezed air from the particle mass flows upward and against the powder flow, reducing the supply of material to the nip area.^[25]

What is the optimum roll speed for a compaction process? What factors does the formulating scientist or process engineer need to consider to maximize compact quality and compaction throughput? Johanson^[29] attempted to answer these questions by predicting roll-limiting speeds for briquetting presses. He developed mathematical expressions considering even the gas and liquid effects as they can theoretically be squeezed from a solid mass. Solid properties, press dimensions, and operating conditions were evaluated to predict optimum roll speeds. The results necessary for a quality briquette are most critical for low density fine particles. Johanson's work showed the relation between feed pressure and roll speed to essentially be proportional to the material's permeability (porosity). For example, when the initial

Fig. 10 Compression feed screw and fixed roll system and no vacuum deaeration. (Courtesy of Bepex-Hosokawa Co.)

powder was compacted, sized, and recompact, the bulk powder permeability increased; however, when the powder was compressed, the compression force decreased, and compactor feed pressure force requirement decreased significantly. Johanson^[29] also demonstrated that if the compactor feed pressure is kept constant and the press speed is increased, the maximum pressure applied to the briquette decreases as the roll speed increases. As a result, the briquette density and strength decrease likewise. For additional information, the interested reader should peruse the reference list.

Sheskey and Hendren in 1999 studied the effect of roll surface configuration on the drug release and physical properties of a HPMC matrix controlled-release dosage form.^[30] Smooth and axial-grooved roll surface designs were studied using a Vector Model TF-Mini roller compactor (Vector Corporation, Marion, Iowa). Their hypothesis was that the greater the depth of the concavity on the roll surface, the pressure exerted on the powder being compacted would not be as evenly displaced as with a smooth roll surface. Therefore, as with tablet tooling design, the top of the crown area of the compacted ribbon would theoretically be softer than the rest of the ribbon. However, the results of a particle size distribution test performed on milled ribbons generated using both smooth and axial-grooved roll pairs showed similarity between tested samples. In addition, results showed little difference in tablet crushing strength values between samples manufactured using either type (smooth, axial-grooved) roll surface design. Drug release profiles of tablets prepared from roller compacted granulations using both

roll surface configurations were also similar. It was noted that the authors did not measure product throughput rates to address the possibility of improved efficiency when using an axial-grooved roll pair vs. a smooth roll pair.

FEED SCREW DESIGN

The consistency and evenness of the powder feed into a roll pair determines to a large extent, how complete a compact is made and ultimately the success of a compaction process. Most roller compacting systems suffer the disadvantage of leakage, i.e., 20%–30% powder particles (depending on the formulation) are not compacted. This primarily occurs because of uneven powder feed and powder slippage between individual loose particles and the roll surfaces. Under these conditions, it is usually necessary to recycle the uncompact powder or fines. Recycling a compaction process is a significant draw back because of additional capital expenditure, labor costs, and increased throughput time.

The chief objective of roller compaction is to consistently make an agglomerate of sufficient strength that meets required density, granulometry, and powder flow specifications. Operationally, the key goal of a compactor is to maintain a range of pressure on the feedstock, independent of the fluctuating powder granulometry and flow fed into the rolls, so that a consistent compact is made.

Typically, the compaction process is managed by controlling the input material, the quantity per unit of time, the roll speed, and the roll gap. Allowing the roll gap to float unchecked can influence the production rate and the compact quality. Therefore, it is important to control the compaction process by setting a constant powder feed rate during the compaction operation.

Design innovations on the powder feed input side of the roller compactor are complex. The complexity is double-edged: powder materials, which flow and move well, are more easily handled on the feed side of the compactor. These types of materials generally do not necessarily need significant densification to marginally improve their flow handling characteristics on a large scale. On the other hand, poor flowing and low density powders require special equipment and considerations to feed a compactor. Additionally, it is necessary to maintain a constant powder flow and quantity of material to the rolls during the compaction process. Therefore, the delivery feed system plays a very important role in delivering poor flowing low density bulk powder materials to the roll compactor.

Johanson, in 1995, described an arch-breaking hopper design that effectively delivered poor flowing powder

from the hopper to a horizontal feed screw. The unique hopper design eliminated the “rat-holing” effect of poor flowing powders during hopper voiding and is described in Fig. 11.^[31]

Miller noted that the total compaction power requirement is the sum of the power required for the feed screw(s) and the roll drive.^[2] Feed screws not only convey the powder material from the compactor storage hopper but they also help deaerate the powder in the process. The deaeration of the powder acts as a mini compactor by precompacting the material just prior to roll compaction. Optimum compaction pressures and feed screw designs vary widely for different powder material properties. Changes in bulk powder density and feed screw speeds will affect the roll gap, the compaction pressure, the throughput, and the quality of the compact.^[2]

Weggel indicated that feed screw torque varies directly with the precompaction pressure.^[32] He suggested that by maintaining a constant feed screw pressure, the compactor operator can control the compact quality. Variations in precompaction pressure and in the compacting pressures are directly related to feed screw amperages and the roll drive motor. The compaction pressures are dependent on a continuous flow of powder into the feed screw area. If the powder feed flow is intermittent or interrupted, this will affect the feed screw amperage readings and eventually the roll drive readings. Weggel noted that force-feeding the material deaerates the feedstock and reduces the roll pressure loads. He found generally that it is more efficient

to achieve maximum densification during several stages of the roller compaction process.^[32]

Miller noted in 1996 that the design of vertical cylindrical feed screws tends to feed powder uniformly to the circumference of the feed screw.^[2] He concluded that the powder feeding to the rolls did not coincide with the general rectangular shape of the compactor throat. The observed draw back was that the powder did not get delivered evenly across the rolls; the middle of the rolls received more powder than the rolls' edge. This potentially created a poor quality compact; a strong middle compact that is weak at the ends because of frayed edges. Frayed compact edges give rise to uncompacted material and excess fines.^[2] An example of the phenomena was depicted when using a light yellow-green color feedstock, which after roller compaction using a twin feed screw system, produced a homogeneous colored compact. The same feedstock passed through a compactor designed with a single vertical feed screw, exhibited a sinusoidal colored compact as shown in Fig. 12.

Guigon and Simon, in 2001, showed a similar phenomenon using a horizontal single feed screw without vacuum deaeration when compacting sodium chloride.^[33]

Miller indicated that a multiple horizontal feed screw design system provided a more uniform powder distribution across the rolls in area and volume than a single vertical feed screw system. This concept applied to either the vertical or the horizontal single feed screw systems.^[2]

DEAERATION THEORY

A key factor limiting compaction throughput and quality is air entrapment in powder materials. During compression, air-occupying voids between particles are compressed and squeezed. The gas pushes through the powder causing powder fluidization and a nonuniform level of powder at the roll gap. It is best described in Fig. 13. This situation limits compact throughput and creates a nonuniform compact density. It also creates excess fines prior to sizing because of “spidering” compact edges.

The spidering condition occurs when gases rush across the inside of a compact to thinly and weakly formed flaked edges. The flake edges break apart perpendicular to the compaction direction. The compact edge breakage appears “saw tooth” in structure and varies in length depending on the nature of the powder binding properties, the amount of air entrainment, and the roll dwell time.

Fig. 13 Pattern of gas escape from roll nip region. (Courtesy of the Institute For Briquetting and Agglomeration.^[35])

Johanson predicted theoretical compactor operating conditions to handle air entrapment effects in materials. In general, he concluded that the critical compacting pressure level is dependent on a number of factors: roll speed, roll diameter, powder permeability, compressibility, and compact strength. Johanson indicated, when applying these principles in commercial application, a compactor operator would have to operate the press at slightly less than maximum pressures to allow for material inconsistencies and variable in-feed flow rates.^[34]

Pietsch, Johanson, and Dec described the forces at work in a roll press when powders are compacted.^[25,34,35] Pietsch, in Fig. 14, illustrated the three typical work phases during compaction.^[25] The first region is the initial solids' contact pressure with the feed screw. Pressure at this point is nil, p_0 . Later, as the solids begin to get pushed into the rolls and gripped by the rolls, pressure continues to build.

Ultimately the solids are moved into the narrowest point of the nip angle where the maximum pressure occurs at p_{max} . The second region describes the solid's density increase through compaction. As is shown in Fig. 14, densification occurs rapidly, in less than a second. Some materials have properties that after discharge from the compactor undergo elastic deformation, which can reduce the compact's density, expressed by the dotted curve. Third region of force at work is air pressure. Models such as the one described take into account that it is dependent on the porosity of the particulate solids compacted. If the porosity of the compacted material remains high enough during the compaction process, air pressure can escape and vent during and after compaction. On the other hand, if the material has low porosity, air pressure builds to high levels because it cannot escape easily. This can be seen in several ways, one of which is through expansion of the compact bursting. Bursting can be associated with a popping sound when operating the compactor. The second way occurs

Fig. 14 Compaction work phases. (Courtesy of the Handbook of Powder Science.^[25])

when the compacted sheet breaks into slivers or “spidering” at the compact edges.

Both Johanson and Pietsch reported that expanding gas in a compact is detrimental to the compaction process: by reducing the compaction throughput and increasing the amount of fine particles. The effects of roll speed and powder porosity on air pressure in a compacted sheet are also illustrated in Fig. 15 by Pietsch.^[25] This graphic shows a relative large roll speed operating range when compacting a permeable (porous) powder. Air entrainment does not limit roller speed for coarse granular powders. On the other hand, when compacting very fine powders, the operating roll speed range is significantly reduced because of air entrainment.

Miller indicated that the evenness of the powder feed into the rolls determines, to a large extent, the success of compaction. Roller compactor systems suffer from two disadvantages: as the powder feed bulk density approaches 0.3 g cm^{-3} or less, the compaction throughput efficiency decreases. Secondly and concurrently, the uncompacted powder leakage generally increases around the rolls.^[22] Miller, in 1994, described a new machine design improvement that used vacuum deaeration to remove air entrainment from the powder just prior to the nip angle during roller compaction. The multiple benefits of such action are significant, and remarkable results have been observed when compacting low density raw materials.^[22]

- More uniform powder feed to the rollers.
- Less voltage and amperage variability for the roll pair.
- More uniform and strong compact.
- Less powder leakage.
- Greater yield.
- Less powder adhering to the compact prior to sizing.
- Higher compact throughput.
- Less airborne particles.

Fig. 15 Effects of roller speed and permeability on air pressure in the compacted sheet. (Courtesy of the Handbook of Powder Science.^[25])

The newly designed equipment involved a compactor fitted with two horizontal feed screws, which featured vacuum deaeration. Specifically, the roll compactor was equipped with a conical storage hopper containing a variable speed agitator. Bulk powder was fed directly from the top of the hopper to the top of twin horizontal auger feed screws, which directly transported the powder to the nip roll area, Fig. 16.^[2]

A novel stainless steel encasing that leads to the compactor rolls encloses the variable speed auger screws. Just before the nip area, a pair of sintered stainless steel segments are assembled within the horizontal auger feed system, which can operate under partial vacuum. A small, self-contained vacuum pump draws negative pressure through a dry filter and a stainless steel line to the sintered assembly plates. The partial vacuum is adjustable from -0.1 bar to -0.8 bar . The compaction rolls operate at different speeds and are supported on heavy-duty bearings in such a way that the lower roll is fixed and the upper roll is slightly movable in the vertical plane. The deaerated material passes through the roll pair, which is under infinitely variable hydraulic pressure. The deaeration, auger feed screws' design and speed, roll speed, and hydraulic roll pressures are the main factors in producing a compact with specified properties.

In several experiments, Miller studied the effects of using horizontal twin auger feed screws under partial vacuum (Alexanderwerk Inc., Horsham, Pennsylvania, model 50/75 compactor). The feed powder was vacuum deaerated just before roller compaction. The experimental design showed that the compactor's deaeration feed system significantly increased compaction output and minimized powder leakage when compacting very low density blends ($< 0.35 \text{ g cm}^{-3}$).^[22]

Fig. 16 Side view of feed screw system and vacuum deaeration with sintered plate segments. (Courtesy of Handbook of Pharmaceutical Granulation Technology.^[2])

To evaluate the effectiveness of the compactor's deaeration system, a test was designed to process a low density active drug blend with and without the activated deaeration system. The test showed how much material was compacted with the deaeration system engaged and how much material was compacted when it was not engaged. The test also determined how much material was not compacted (powder roll leakage) in each case. During multiple trials, weighed powder blends (0.25 g cm^{-3} – 0.35 g cm^{-3} density) were processed with the deaeration system engaged. The material was compacted at a specific screw feed rate, roll speed, and roll pressure. The compacted material was not sized. Instead, it was carefully collected on a 10 mesh screen to determine the compact and leakage quantities. In the first experiment, under the influence of vacuum deaeration, the compactor produced throughputs of 100 kg hr^{-1} and the resultant noncompacted material leakage rate was $< 2\%$. The vacuum deaeration was so effective, resulting in only limited leakage of noncompacted material, there was no need to recirculate the noncompacted powder back to the rolls to meet processing specifications.

Under a second set of compacting conditions, vacuum deaeration was not activated and the process typically produced 70 kg hr^{-1} – 80 kg hr^{-1} of densified compact. The powder leakage rate increased to 20%–30%. During this set of conditions, the powder flow to the roll pair was uneven and the ribbon compact was not uniform. Processing this formulation for a long period of time under these conditions would have required recirculation equipment to return the uncompacted powder to the rolls for further processing.^[22,36,37] The compactor parameters are described in Table 3 (Trials 1 and 2).

A second experiment was conducted with a different formulation involving the same active drug substance and the same active quantity per unit dose. This experiment replicated the design of the first experiment. The powder feed was processed and compacted with and without vacuum deaeration. The rates of compaction were

measured in the same manner as the first experiment. The compaction parameters were purposefully optimized at a roll speed of 8 rpm. The compactor yielded 150 kg hr^{-1} and the powder leakage rate was only 0.9% using the deaeration system. The compaction process typically produced 100 kg hr^{-1} – 110 kg hr^{-1} with 20%–30% powder leakage when vacuum deaeration was not in use. Table 4 (Trials 1 and 2) contains parameter settings and comparative results.^[22,36,37]

Both experiments clearly demonstrated the importance of vacuum deaerating the bulk powder just prior to compaction. In addition, the second formulation provided increased compaction throughput (with or without the vacuum deaeration) compared to the first formulation. The research formulators had improved the compaction rate by reducing the powder blend fluidization level (defined as the amount of powder airborne at a specific agitation rate) without changing the bulk density or other bulk parameters. Miller noted that the fluidization level appeared to be a key parameter that should be minimized to improve compaction yield rates.^[22]

In several other trials, Miller also studied the effects of using two different compactors' vacuum deaeration systems. The tests, similar to the ones previously described in this section, were carried out using differently designed compactors (employing and not employing vacuum deaeration). The objective of these trials was to increase the active bulk density of the feedstock from 0.22 g cm^{-3} to 0.61 g cm^{-3} .^[2]

Miller reported that the compactor, machine one, containing the horizontal twin screws and the vacuum deaeration design as described in Fig. 16, produced granules with 0.63 g cm^{-3} – 0.64 g cm^{-3} density at 80 kg hr^{-1} yield. When the vacuum deaeration was not activated the desired granule density specification could not be achieved. See Table 5 (Trials 1 and 2) for operating parameters and results of compactor machine design one.

A second compactor, machine 2, Fig. 17, did not densify the active drug granules during the first

Table 3 Compactor operating conditions and throughput yields for poor flowing low density active drug blend, formulation 1, vacuum deaeration and nonvacuum deaeration trials

Conditions	Trial 1	Trial 2

compaction run when employing vacuum deaeration. After a second compaction pass with vacuum deaeration, Trial 2, the powder density was increased slightly to 0.58 g cm^{-3} . It appeared that the level of vacuum being applied to the active drug substance, in machine 2, was insufficient, ineffective, or not optimally positioned, (even at its maximum vacuum deaeration level) to effectively help predensification.^[2] See Table 6 (Trials 1, 2, and 3) for machine two operating parameters and results.

Miller's experiments evaluated the effects of powder density, screw feed speed, roll speed, roll pressure, vacuum deaeration pressure, compaction rate, and the compaction leakage rate. Test results demonstrated that the first compactor's deaeration and feed system designs significantly increased compaction output. The new equipment design and process provided high compact yields and virtually eliminated powder leakage, obviating the need for expensive powder recirculation equipment. Compactor one's vacuum deaeration design (Fig. 16) proved to be

superior to the second (Fig. 17) when compacting an active bulk drug with a density of approximately 0.2 g cm^{-3} . In summary, a new critical condition, vacuum deaeration, had been identified in optimizing roller compaction effectiveness and efficiency.^[2]

Miller concluded that four key processing conditions must exist to optimize roller compaction throughput and minimize powder leakage around the rolls:^[2]

- Adequate powder supply must enter the gripping zone.
- Powder must be fully conveyed into the narrowest part of the roller gap.
- Compaction pressure must be distributed as uniformly as possible over the whole of the roller-gripped powder mass.

**Fig. 17** Compactor front view of vertical feed screw system with vacuum deaeration. - Sufficient vacuum deaeration must be effectively distributed prior to the nip roll region, particularly for low bulk density powder feed stock.

SIZING COMPACTS

There are no published studies describing compactor-milling studies. The theory of comminution or size reduction is well written about by Rekhi and Vuppala.^[38] They described the criteria for mill selection, mill classification, and variables affecting the sizing process and scale-up. The interested reader is also recommended to peruse Parrot, Johnson, and Lantz.^[39–41]

EQUIPMENT FEATURES

A closer look at state-of-the-art roller compactors now available for the pharmaceutical industry is described in the following pages. Careful attention to detail was taken by the authors to represent the key industrial compactors' feature designs. Electronic pictures and equipment descriptions were obtained from the equipment manufacturers. This was the best way to fairly represent each company's machine design characteristics and features, facilitate the subject matter, and make the chapter factual and meaningful for the reader. All of the equipment innovations presented offer high levels of process control, throughput efficiency, safety, and a quality product. In this section, sizing equipment will be referenced but not described in detail.

The Alexanderwerk Inc. roller compactor (Fig. 18) is modular designed with a horizontal twin feed screw system that feeds two cantilevered rolls positioned vertically (6 and 12 o'clock). One roll is fixed and the other floats; the rolls can be cooled. The horizontal feed screws are specially enclosed in a stainless steel shroud that contains a unique vacuum deaeration system. Operator interface screens allow for on-line monitoring and controlling feed screw speed, roll gap and pressure, and sizing granulators. Diagnostic feature functions are displayed on-line, such as operation, maintenance, and calibration. All functions are interfaced and adjustable through PLC for process control and report monitoring. The two sizing granulators (coarse and fine units) are in series and integral to the compactor.

The Gerteis Co. roller compactor (Fig. 19) consists of three main units: feeding system, compaction, and granulating units. Feeding and tamping augers transport the powder to the compacting area and the machine is fitted with vacuum deaeration. Monitoring and controlling the roll force, gap distance, as well as the speed and torque distribution between the rolls can be adjusted through PLC for process controls. The rolls are mounted at an angle 30° to the horizontal plane; one roll is fixed, the other floats and they are cantilevered. The sizing unit is attached to the machine and consists of two prebreakers, a rotor with and interchangeable roll, and sieve basket. The system has interface capability to collect data for process documentation. The rolls can be cooled and the machine has CIP capability.

The Fitzpatrick Co. roller compactor (Fig. 20) features two feed screws in series: one horizontal and the second vertical. This system is designed to transfer powder bulk into a set of cantilevered rolls positioned in the horizontal mode; one is fixed, the other floats. Operator interface allows for on-line monitoring and controlling feed screw speeds, roll pressure, and roll gap. Features such as on-line help and diagnostic functions, maintenance, and calibration screens are displayed. All functions are interfaced

Fig. 21 Fixed rolls on two bearing blocks, rolls are concave. (Courtesy of Bepex-Hosokowa Co.)

and adjustable by PLC for process control and report generating. The machines have vacuum deaeration and roll cooling capabilities. The sizing unit is separate from the compactor and is either a rotor bar or a hammer mill.

Bepex-Hosokowa Co. compactor (Fig. 21) consists of a pair of rolls that are both fixed and not cantilevered. The rolls are mounted on a horizontal plane in fixed bearing blocks and there is a set fixed gap distance. The Bepex roll designs are concave and can be water cooled.

A specially designed compression feed screw and upper arm assembly are shaped to closely conform to the inner wall of the feed hopper. The feed screw (usually noncylindrical) has uniquely pitched edges. The feed screw design features and gravity aid to drive the powder-stock into the compaction area. There is no vacuum deaeration system. Predensification and deaeration occur in the screw feed region during operation.

Monitoring and controlling the roll speed and force and the feed screw speed and torque are adjusted through PLC for process controls. Prebreaker and flake crushers are attached sizing features. CIP capability exists.

Vector Co. compactor (Fig. 22) consists of cantilevered rolls that are mounted on a horizontal plane; one roll is fixed, the other floats. The feed screw designs are specially tapered and consist of noncylindrical and cylindrical

Fig. 22 Cantilevered compactor with one fixed and floating rolls, no vacuum deaeration, sizing device not attached. (Courtesy of Vector Co.)

shapes. Monitoring and controlling the roll force and speed, gap distance, as well as the feed screw speed and torque can be adjusted through PLC for process controls. There is no vacuum deaeration system. Predensification and deaeration occur in the screw feed region during operation. The Vector compactor rolls can be water cooled. The feed screw design features and gravity aid to drive the powder-stock into the compaction area.

ACKNOWLEDGMENTS

The authors gratefully acknowledge and thank Carol G. Miller for her contributions and assistance in editing and data manuscript control. The authors thank Dr. Pierre Guigon, Professor and Director of Chemistry at University of Technology of Compiègne France for his collaborative contributions to the text. SCALE-UP AND POSTAPPROVAL CHANGES (SUPAC)

Jerome P. Skelly

Consultant, Alexandria, Virginia, U.S.A.

OVERVIEW

In the process of developing a new drug product, the batch sizes used in the earliest human studies are small. As one proceeds through Phase 1 testing (i.e., the first introduction of a new chemical entity to humans), Phase 2 (discovering an indication for use), and Phase 3 (determining dose, side-effect profile, etc.), the size of the batches is gradually increased. When a New Drug Application (NDA) is approved by the Food and Drug Administration (FDA), the drug product is scaled up to a significantly larger batch size to meet the demands of the anticipated market. Similarly, in the development of a generic version of an already approved marketed product, a small batch is produced and tested for, among other things, bioequivalence to the FDA reference listed drug product. When the generic product meets FDA approval criteria, the Abbreviated New Drug Application (ANDA) or generic antibiotic application (AADA) is approved for marketing. It, too, is then scaled up to meet the demands of its anticipated market.

Whether a new chemical entity being brought to market for the first time or an approved generic version of previously marketed product, the size of the batch is almost inevitably scaled up to a significantly larger batch. In the process of scaling up, certain changes in the formula (composition) and/or in the manufacturing process and/or in the equipment may be necessary. In addition, the site at which the product will be manufactured may differ from where the smaller (pilot) batches were manufactured. The scale-up process and the changes made after approval in the composition, manufacturing process, manufacturing equipment, and change of site have become known as Scale-Up and Postapproval Changes, or SUPAC. The FDA has issued various guidances for SUPAC changes designated SUPAC-IR (1) (for immediate-release solid oral dosage forms), SUPAC-MR (2) (for modified-release solid oral dosage forms), and SUPAC-SS (3) (for non-sterile semisolid dosage forms including creams, ointments, gels, and lotions).

Although scale-up may occur at any point in the lifetime of a product, it most often occurs after the firm has been notified that the drug product is approvable, i.e., it meets all the conditions required by the FDA for marketing. With

the submittal of Final Printed Labeling, a showing that the marketed product will meet the conditions for marketing as approved by the FDA (and in the case of generics, production of three consecutive scaled-up batches), and satisfactory completion of a preapproval inspection by the local FDA district office, the product is formally approved to be manufactured and sold in the United States. At this point, SUPAC begins to exert its effect.

Although SUPAC is a means of decreasing regulatory burden by empowering industry to make regulatory decisions, it does not affect any compliance or inspection requirement. It also is limited to scale-up and postapproval changes, even though the underlying science applies to preapproval changes as well. The major affect of SUPAC is a significant decrease in the time required to implement changes.

BACKGROUND

For years, the FDA had approved generic drug applications (ANDAs), using bioequivalence as a surrogate for clinical effectiveness. Aware that changes in the scale of the batch or the manufacturing equipment could affect a product's bioavailability, the FDA required that batches used in the ANDA-submitted bioequivalence studies be "production-sized batches made on production equipment." The FDA failed to verify the truthfulness of this statement, which had been submitted in virtually every ANDA and AADA. At one point, however, FDA inspectors noted that one firm, having obtained approval of a generic version of an approved marketed drug, had great difficulty scaling up that product to market-size batches. On investigation, the FDA discovered that the production-size batch made on production equipment consisted only of a few hundred dosage units produced on laboratory equipment. Although the samples from this very small batch when tested were bioequivalent to the innovator product, the firm could not scale up to the million plus units per batch they wished to market.

The FDA immediately promulgated rule 22-90, requiring that the minimum batch size for bioequivalence studies would henceforth be 100,000 units or 10% of

the anticipated market batch size, whichever is greater. Although this rule solved an immediate problem, it was not based on science. To address the question, the FDA used a method previously used to address quite controversial issues involving controlled-release dosage forms (4, 5) and bioanalytical methods (6). With the American Association of Pharmaceutical Scientists, it held three public workshops, bringing together outstanding industrial, academic, and FDA scientists to openly discuss the scientific and regulatory issues. The discussions were followed by the publication of consensus White Papers (7–9).

SUPAC

The premise of the consensus White Papers was that if: 1) the source of the drug substance for the smaller and larger batches was the same; 2) the drug substance particle size (both mean and distribution) was the same; 3) the excipients were the same; 4) the excipient particle size (both mean and distribution) was the same; 5) the order of addition was the same; 6) the equipment was the same; 7) the processing was the same; and, most important, 8) a surrogate test for bioequivalence testing (dissolution) was the same, the two batches were indeed the same. Over the previous 20 years the FDA Biopharmaceutics Program had established that within definable limits, dissolution was predictive of in vivo bioequivalence, for the same formulation, processed under the same conditions, on the same equipment. These criteria became the fundamental principle of the SUPAC initiative. (The percutaneous diffusion test is similarly used as a surrogate bioequivalence test for nonsterile, semisolid formulations.)

To establish the validity of the approach recommended by the three consensus papers, the FDA contracted the College of Pharmacy of the University of Maryland to study several drug products chosen on the basis of their solubility and permeability. The data revealed that the workshop recommendations were conservative and could be safely implemented. In fact, the studies showed that even broad differences in in vitro dissolution that resulted from major compositional changes failed to translate into bioavailability differences. Subsequently, the FDA published its *SUPAC Guidance for Immediate Release Solid Oral Dosage Forms* and followed with guidances for modified-release (controlled-release) and nonsterile semisolid dosage forms. In November 1999 (modified slightly in December 1999), the FDA extended the SUPAC concept to address changes in analytical methodology, packaging, and labeling and sterile semisolid dosage forms (10). This last guidance also updated the previously published guidances

on immediate-release, modified-release, and nonsterile, semisolid dosage forms. In particular, the issue of multiple postapproval changes (which had been addressed differently in the previously published guidances) were now the same. The FDA now allowed multiple postapproval changes for every solid oral dosage form, using the same requirements as its SUPAC Semisolid Guidance.

The SUPAC Guidances published by the FDA define various levels of change and for each level of change specifies the 1) recommended chemistry, manufacturing, and control tests; 2) in vitro dissolution testing and/or in vivo bioequivalence tests; and 3) documentation that the FDA requires to be filed in the NDA, ANDA, or AADA to support the change. These guidances do not affect other compliance or inspection documentation required by the FDA Center for Drug Evaluation and Research Office of Compliance (CDER-OC) or the FDA field investigation units.

DOCUMENTATION

An annual report must be filed for every active application pending at the FDA. This report, which must be filed annually, updates all activity covered by the various FDA regulations affecting drug products under development or approved for marketing in the United States. Any change to an FDA-approved product must be submitted in a Supplemental New Drug Application, which requires review and approval. Until SUPAC, all supplements were Prior Approval Supplements (PAS). However, with SUPAC, the Agency allowed the use of a new Changes Being Effectuated (CBE) supplement, which allows industry to implement certain moderate changes on the very day the supplement is sent to the FDA. This eliminated the previously required and often lengthy FDA prereview and comment period. On the other hand, the Agency, after its review, reserves the right to require a PAS rather than a CBE if it disagrees with the industry decision. When the FDA published its new and updated guidance in December 1999, it provided for a new supplemental application called Changes Being Effective in 30 days (CBE-30). This procedure primarily applies to sterile dosage forms for which the Agency, obviously, requires a more exacting level of review.

LEVELS OF CHANGE

SUPAC lists three levels of change (Fig. 1) including: 1) minor changes, which are unlikely to have any

Fig. 1 Levels of change to FDA-approved products.

detectable effect on formulation quality and/or performance; 2) moderate changes, which could have a significant effect on formulation quality and/or performance; and 3) major changes, which are quite likely to have a significant effect on formulation quality and/or performance of the dosage form.

For a minor change, the chemical testing required and submitted to the FDA is routine. For example, accelerated stability testing and a commitment to perform long-term stability testing, plus those tests contained in the compendia and/or in the NDA/ANDA/AADA, would have to be performed. The data must be filed in the next annual report. On the other hand, a major change could involve dissolution-testing profiles to be determined in several media, an *in vivo* bioequivalence study, and a requirement for all data to be submitted in a supplemental filing to the application, which would require FDA preauthorization before implementation.

CHEMICAL, MANUFACTURING, AND CONTROLS TESTS

The FDA chemical testing for immediate-release, solid oral dosage forms (including the surrogate dissolution test) takes into consideration whether the drug has a narrow therapeutic index. The chemical, manufacturing, and control testing (including dissolution) is more onerous for narrow therapeutic index drug products than for other immediate-release, solid oral dosage forms.

In addition, although the testing criteria for changes in the composition of nonrelease-controlling excipients in delayed release (i.e., enteric-coated) dosage forms and controlled-release (i.e., extended) dosage forms are very similar to those for immediate-release, solid oral dosage forms, the criteria for those excipients affecting the release rate are, understandably, more onerous.

On the other hand, the comparability of the drug substance and excipients with those of the innovators product listed by the FDA as the "Reference Listed Drug"

(RLD), assumes (under the FDA's SUPAC guidelines) considerably greater importance for sterile and nonsterile semisolid formulations than, for solid oral dosage forms. With the semisolid dosage forms, the FDA uses various types of diffusion analyses in lieu of dissolution as a surrogate for *in vivo* bioequivalence.

In general, semisolid dosage forms are complex formulations having complex structural elements. Often, they are composed of two phases (oil and water), one of which is a continuous (external) phase and the other of which is a dispersed (internal) phase. The active ingredient is often dissolved in one phase, although occasionally the drug is not fully soluble in the system and is dispersed in one or both phases, creating a three-phase system. The physical properties of the dosage form depend on various factors including the size of the dispersed particles, the interfacial tension between phases, the partition coefficient of the active ingredient between phases, and the product rheology. These factors combine to determine the release characteristics of the drug as well as other characteristics such as viscosity.

Although for a true solution, the order in which solutes are added to the solvent is usually unimportant, this is not true for dispersed formulations. Because dispersed matter can distribute differently depending on the phase to which a particulate substance is added, the order of addition for these formulations is of critical importance. Any change in the order of addition, therefore, is a major change.

Over a period of years, the FDA, monitoring the performance of a variety of physical and chemical tests commonly performed on semisolid products and their components (e.g., solubility, particle size, and crystalline form of the active component; viscosity; and homogeneity of the product), has determined that these tests provide evidence of consistent performance. Although the evidence available at this time is less convincing than *in vitro* dissolution as a surrogate for *in vivo* bioequivalence in the case of solid oral dosage forms, the FDA is using diffusion testing (i.e., *in vitro* release-rate testing) to assess product "sameness" to allow certain SUPAC for semisolid products.

STABILITY

In addition, the FDA requires that every marketed product be stable, meeting its approved specifications throughout its marketed shelf-life. Generally, for minor changes, in addition to the application or compendial chemistry and manufacturing control requirements

(CMC), long-term stability data from one batch must be filed when available in the annual report. For moderate changes, the general requirement is for accelerated (3-month) stability data from one batch filed in either a CBE supplement or a PAS, plus long-term stability data from one batch filed in an appropriate annual report. For major changes, in addition to the long-term stability data for one batch filed in an annual report, 3-month accelerated stability data must be submitted in a PAS for either one or three batches, depending on how long that particular product has been in the marketplace. For new chemical entities, the period is 5 years, whereas for a new dosage form of an approved chemical entity, the period is 3 years. If the product meets this market criterion, a "substantive body of information" is said to exist, and data from one batch are required to be submitted. If a product does not meet this marketing criterion, a "significant body of information" is said not to exist, and data from three batches are required to be submitted. In any case, the data must be filed in a supplement requiring FDA preapproval (i.e., PAS).

SURROGATE MEASURES OF EFFICACY

For 30 years, the FDA has satisfactorily used in vivo bioequivalence as a surrogate of clinical efficacy for the development of new dosage forms and strengths of innovative products and for approval of generic versions of approved marketed drugs. It additionally requires human in vivo bioequivalence studies for most major postapproval changes, as well as for moderate postapproval changes for narrow therapeutic index drugs. In those cases where an in vivo/in vitro correlation has been established for a particular product, it may be used in lieu of in vivo bioequivalence.

However, the FDA uses in vitro dissolution as a surrogate for in vivo bioequivalence testing for most minor and moderate postapproval changes. For implementation of minor changes, the dissolution requirement is usually the same as that required by the FDA for the release of an approved product into the marketplace. On the other hand, for moderate changes, the FDA usually requires additional in vitro dissolution testing. The type of dissolution study required for solid oral dosage forms varies depending on several drug variables, e.g., solubility, permeability, therapeutic index, and dosage form.

Minor changes may be implemented for drugs that are both soluble (at the largest strength marketed) and permeable (bioavailability >90%) if the product meets

the SUPAC single-point dissolution criteria of 85% in 15 minutes. Those that fail this test must meet a more onerous multipoint dissolution test in which samples are taken every 15 min until either 85% is dissolved or an asymptote is reached, thus establishing a dissolution rate profile. Modified-release preparations must additionally meet the profile criterion in water and buffered aqueous solutions. The dissolution profiles comparing product manufactured after the change with that manufactured before the change must be comparable. The FDA accepts comparability if the profiles meet the FDA "F-2" similarity test criterion (11). Failure to establish comparable dissolution profiles would normally necessitate human in vivo bioequivalence studies or use of an in vivo/in vitro correlation. In addition delayed-release solid oral dosage forms must pass the compendial 2-h acid-dissolution test.

In the case of semisolid dosage forms, the FDA uses a standard open-chamber diffusion cell fitted with a synthetic membrane as the in vitro release test to be used as a surrogate for in vivo bioequivalence studies. It uses this test for semisolid dosage form SUPAC changes, just as it used dissolution in the case of solid oral dosage forms. The FDA guidance recommends using the test on all creams, ointments, and gels. In this test, a plot of the amount of drug released per unit area of membrane ($\mu\text{g}/\text{cm}^2$) versus the square root of time should yield a straight line. The regression (slope of the line) represents the drug release rate. Comparisons of the release rate before and after making the change are required. In the case in which the change is not similar, in vivo bioequivalence data would be required to implement the change.

POSTSCRIPT

SUPAC is a revolutionary change in drug regulation. For nearly all of the 20th century, congressional action increased industry's regulatory burden in response to what was perceived as industry's irresponsible actions. This was accompanied by an ever-increasing cost to develop and market new drugs and a concomitant increase in the time required to obtain marketing approval from the FDA. In the last 2 decades, many perceived that the United States was falling behind in the drug development process and that, as a result, Americans were not able to obtain new state-of-the-art treatments for serious diseases in timely manner. With the passage of the Food and Drug Administration Modernization Act (FADAMA), Congress allowed the FDA to employ

additional scientists while at the same time mandated management efficiencies in the drug review process. SUPAC is a reversal of the ever-increasing authority of the U.S. drug regulatory body. It empowers the industry to take responsibility for its actions, while simultaneously allowing adequate overview of the drug development and marketing process by the FDA.

Because of FADAMA, the SUPAC process has been extended by the FDA to include sterile dosage forms, analytical methods, product labeling, and product packaging postapproval changes.

Two important updates of previously published SUPAC guidances include the change in multiple SUPAC changes and the redefinition of "site of manufacturer". For all SUPAC guidances, multiple postapproval changes are now permitted. The requirements that must be fulfilled default to those for the most restrictive change proposed. For example, three level-one changes and one level-two change would have to meet the more restrictive level-two criteria.

In addition, although the definition of "same site/different site" will remain the same for foreign manufacturers until a May 14, 1999, proposed regulation requiring registration of foreign manufacturers who want to market drugs in the United States is published in final form, the definition for domestic manufacturers has been changed. In the latter case, Same Site is defined as the site in which the new and old buildings are included under the same drug establishment registration number, and the operations in both are inspected by the same FDA district office. Different site is defined as the site where the new and old buildings have different drug establishment registration numbers or when the operations are inspected by different FDA district offices.

SECONDARY ELECTRON MICROSCOPY IN PHARMACEUTICAL TECHNOLOGY

Peter C. Schmidt

University of Tübingen, Tübingen, Germany

BASIC PRINCIPLES OF ELECTRON MICROSCOPY

Introduction

Basic principles of imaging

The principle of an electron microscope is based on the light microscope except that electrons are used instead of light. The resolving power of any microscope is given by Abbe's equation:

$$d_0 = \frac{0.61 \cdot \lambda}{n \sin \alpha} [\text{nm}] \quad (1)$$

where d_0 = minimum resolvable separation distance; λ = wavelength of the light; n = refractive index of the medium between the object and the objective lens; and α = half-angle subtended by the objective at the object.

The lower the minimum resolvable distance the higher the resolution of the instrument. Therefore, the resolution is enhanced by a short wavelength of the light, a high refractive index of the medium between the objective lens and the object, and a small distance between the object and the lens. The product $n \sin \alpha$ is called the numerical aperture of the objective lens. Since α can never exceed 90° , an objective in air can never resolve distances smaller than 0.61λ . The limits of a light microscope are given in Table 1.

De Broglie (2) showed that an electron has a dual character. It can be regarded either as a moving charged single particle or as a radiation with a distinct wavelength. The relation between the two is given by Eq. 2:

$$\lambda = \frac{h}{mv} [\text{nm}] \quad (2)$$

where λ = wavelength; h = Planck's constant; m = mass of the electron; and v = velocity of the electron.

The velocity of the electron depends on the voltage applied and can be used to calculate the wavelength, λ , and the minimum resolvable distance, d_0 , as shown in Table 2.

The advantage of the use of electrons as a light source compared with visible light is obvious.

Types of electrons in electronic imaging

When an electron beam is interacting with a specimen surface, different reactions can occur. The various signals arising from the specimen's surface on incidence of the primary electron beam are shown in Fig. 1.

Secondary electrons (SEs): A collision of electrons from the primary electron beam with the surface of the specimen results in a detachment of the so-called SEs. The number of SEs depends on the surface topography, the accelerating voltage, and the atomic number of the surface elements. They create the SE current, which is collected for imaging.

Backscattered electrons (BSEs): These are primary electrons that have been reflected from the specimen surface in a way that they return back out of the specimen again. Depending on the individual collision, they have energies ranging from the full primary energy of the electron beam down to the level of secondary electrons. Their intensity increases with increasing atomic number. They give information on the topography of the sample and the atomic number of the sample elements.

X-ray photons (X): Photons of X-radiation are emitted from the specimen under electron bombardment. They are characteristic for elements and could be used to determine the element distribution on the surface of the sample under investigation.

Transmitted electrons (TEs): TEs are those penetrating through a thin specimen that are focussed into images on a phosphor luminescence screen or on a photosensitive material.

Absorbed electrons (AEs): Some of the primary electrons are absorbed by the specimen and are grounded as a current. If there is no ground connection, the specimen will charge up.

Cathodoluminescence (CL): This is a light emission of the specimen under electron bombardment. The light could be visible or invisible.

In secondary electron microscopy (SEM), in most cases, SEs are used for imaging. BSE detectors are closely connected with element analysis of the specimen. Other types are more or less seldom used in electron microscopy.

Table 1 Minimum resolvable distance, d_0 , of a light microscope depending on the wavelength λ , the refractive index n , and the angle α

Wavelength λ (nm)	Angle α (°)	Refractive index n	Minimum resolving distance d_0 (nm)
800	15	1.000 ^a	1885
400	15	1.000 ^a	942

In transmission electron microscopy (TEM), transmitted electrons will be processed to give an image.

Secondary Electron Microscope

Among the different types of electron microscopes such as the secondary electron microscope (SEM), the transmission electron microscope (TEM), the scanning transmission electron microscope (STEM), and the field emission scanning transmission electron microscope (FESTEM), the SEM finds greater application in the field of pharmaceutical technology, followed by the TEM. This article will focus only on the principle of the SEM.

The design of a SEM is shown in Fig. 2.

It consists of the electronic gun (1), the Wehnelt cylinder (2), the anode (3), and beam alignment coils (4) on the top of the instrument. The condensor lenses (5), the aperture, and the objective lens (6) focus the beam onto the specimen that is mounted on the specimen holder (7). The latter one could be moved in X-, Y-, and Z-direction within the specimen chamber. In addition, the sample could be moved by rotation. The arrangement to create the electronic beam is shown in Fig. 3.

The electrons are emitted by the cathode (1) from a filament, normally a heated tungsten wire. The emitted electron current is controlled by a Wehnelt cylinder (2) having a negative polarity against the cathode. The electrons are picked up by the anode (3) after being

Fig. 8 Microcrystalline cellulose (Vitacel) (top), dicalcium phosphate dihydrate (Bekapress D2) (middle), and dicalcium phosphate anhydrous (Dicaphos AN) (bottom).

accelerated by the accelerating voltage of approximately 1–25 kV. The cathode assembly and the anode are arranged so as to produce a crossover of the electron beam between the components. Through the bore hole of the anode the electron beam enters two electromagnetic condensor lenses (4 and 5), which reduce the crossover. After passing the aperture (6), the electron beam is focussed by the objective lens (7) so that the focal spot is imaged on the specimen surface (8).

The specimen is scanned point by point by the electron beam as shown in Fig. 4. Secondary electrons that are emitted from the specimen's surface (1) are collected by the detector (2) and undergo a video processing (3) leading to the image formed on the video screen (4).

The electron beam is moved on the surface of the specimen by an electromagnetic deflection system that is integrated in the objective lens moving the beam in a raster over the specimen as mentioned above. The deflection system consists of two sets of crossed saddle coils for deflection in X and in Y direction. The saddle coils produce distortion-free images at lowest magnifications and permit large deflection angles.

The secondary electron detector (Fig. 5) (4) is mounted to the side of the microscope chamber. Primary electrons

(PEs) liberate secondary ones (SEs) from the specimen's surface, which are caught by the collector (4) having a positive potential for the detection of SE. The electrons pass through the grid and move toward the scintillator (3). This is biased to +10 kV and accelerates the low-energy SEs to a higher energy level. These electrons strike the scintillator, where they generate photons, which are guided out of the detector chamber through a light guide (2) to the photomultiplier (1). The photomultiplier converts the light current by amplification again into an electron current that presents the video signal at the output of the subsequent preamplifier. If the collector is at a negative potential, only backscattered electrons (BSE) can strike the scintillator and a BSE image is produced in this mode.

Electrons move over long distances only under vacuum. The whole system, therefore, has to be operated under a vacuum of 10^{-5} to 10^{-7} hPa. The vacuum system consists of a rotary pump giving a vacuum up to 10^{-3} hPa combined with a water-cooled turbomolecular pump leading to the desired high vacuum. In some instruments, an oil-diffusion pump is used instead of a turbomolecular pump. An automatic control ensures that the system cannot be run without water cooling and at a low vacuum level.

SAMPLE PREPARATION IN SCANNING ELECTRON MICROSCOPY

Introduction

Most of the samples being investigated by SEM in the field of pharmaceutical technology are powders prepared by different methods, granules, pellets, tablets, and films from coated tablets. The sample preparation of bulk materials includes the following steps:

1. choosing a representative sample from the bulk material;
2. mounting the sample on a suitable sample holder (specimen); and

3. preparing the specimen for observation by coating, if it is not self-conducting.

In pharmaceutical technology, materials are handled quite often as a bulk. Due to the fact that electron microscopic imaging is based on very small samples, the sampling procedure itself and the preparation of the final sample become very important. An overview for sampling procedures is given by Sommer (5). A scheme for powder sampling is given in Fig. 6.

The initial samples from the original bags are normally taken by hand. Depending on the size of the bag they have to be taken from different places. They are then combined by mixing before undergoing the sampling procedure.

Fig. 10 Lactoses. α -lactose monohydrate (top), β -lactose (middle), and spray-dried lactose (bottom).

Today, these procedures are carried out by sampling machines like a rotary sample divider.

Depending on the size of the combined sample, the procedure has to be done in several steps if necessary. At the end a sample size directly applicable to the microscopic sample preparation must be achieved.

Specimen Preparation for Secondary Electron Microscopy

In pharmaceutical technology, most of the samples that are examined by an SEM are powders. After the sampling procedure, the final sample has to be distributed

uniformly onto a stub and later on—if it is not self-conducting—covered by a layer of a conducting material. The stubs are either pin-type mushroom or cylinders normally made from aluminum. In most of our work, simply metal rivets were used instead of the expensive aluminum stubs offered by the suppliers of SEM accessories. The stubs have to be cleaned carefully by a surfactant solution followed by distilled water and acetone in an ultrasonic bath. Finally, the traces of acetone should be removed by a warm air stream. The surface of the stubs is then covered by a double-adhesive tape. Conductivity of the tape is ensured by a small droplet of conducting silver fluid, which is placed between one end of the tape and the stub. Coarse powders

Fig. 11 Sugar alcohols. Mannitol, crystalline (top), mannitol, spray dried (middle), and sorbitol-instant, spray dried (bottom).

are directly sprinkled onto the so-prepared stubs, and fine ones have to be desagglomerated. Depending on the degree of agglomeration this could be done either by blowing the material onto the stub by an air stream or by sucking it through a pipe by vacuum. Also, the “Rhodos” dry powder desaggregation unit of the Sympatec-Helos Particle Sizer (6) could be used to blow the powder onto a stub. Other samples like tablets, coated tablets, pellets, packaging materials, and needles of syringes can be directly mounted to the stub by the use of colloidal silver paste, bonding the sample to the stub mechanically and electrically. For other preparation methods the reader is recommended to refer to a special literature (7).

A part of the primary electron beam, amounting 10^{-12} to 10^{-6} A, is emitted as secondary or backscattered electron current. The difference between the two currents must be allowed to leak away to earth via the stub, otherwise the specimen will charge up. If a sample is not self-conducting it has to be provided with a thin conducting coat. Only at a low accelerating voltage in

the range of 1 kV, a sample does not need to be conductive. The coating is performed under vacuum either by evaporating carbon, gold/palladium, or platinum or by d.c. sputtering. The latter is the most popular and easy technique to apply conductive coatings to a sample. The principle of sputtering is shown in Fig. 7.

The apparatus consists of an evacuated chamber, a cathode, and an anode. The air within the chamber is replaced by an inert gas, preferably argon, and the voltage applied to the system is in the range of 1.0–2.5 kV. Under these conditions a glow discharge is set up between cathode and anode. Neutral gas atoms are ionized to positively charged argon ions and electrons. The ions are attracted by the cathode, where they cause an emission of a gold atom and an electron from the cathode material. The electron neutralizes an argon ion, the Au atom is moving toward the anode. On the way there are a lot of collisions with gas atoms and as a result the Au atoms arrive at the anode from different directions where they settle onto the specimen's surface. Free electrons are accelerated in

Fig. 12 Different types of sorbitol.

Fig. 13 Ludipress (93% α -lactose monohydrate, 3.5% soluble povidone, 3.5% cross-linked povidone) (top), Cellactose (75% α -lactose monohydrate, 25% powdered cellulose) (middle), and Avicel PH 200 (agglomerated microcrystalline cellulose) (bottom).

the direction of the anode, and when reaching the anode, create heat in the specimen.

The process itself and the deposition of metal atoms onto the specimen's surface depends on the target material, the type and pressure of the inert gas within the

Fig. 14 Compressional pressure/hardness-profile and compressional pressure/disintegration profile of the coprocessed materials, Ludipress, Cellactose, and Avicel PH 200.

chamber, the cathode potential, the current, the time of sputtering, and the distance between the target, and the sample. The preferred gas is argon, having the lowest price of all inert gases. Air could not be used because it causes oxidation of metals, e.g., gold. A black coating indicates the presence of air during the sputtering process. With argon the sputtering rate of gold and silver is high compared with carbon. The coating thickness is determined by the sputtering rate, the distance between the target and the sample, and the time. There is a linear correlation between the thickness of the gold layer and the sputtering time at constant conditions.

The quality of the coat has to be judged by the homogeneity of the thickness, adhesion onto the surface of the sample, and its mechanical stability. Plain surfaces result in a uniform coating thickness. At rough surfaces, a uniform coating can only be achieved when the metal atoms settle diffuse from all directions. This could be predetermined by the vacuum applied. The optimum coating thickness is a compromise between the conductivity of the coated sample and the resolution of fine surface structures. If the conductivity is not high enough, a charge up of the specimen is observed. For

routine imaging a coating thickness of 1 to 2.0 nm is sufficient.

APPLICATION OF SECONDARY ELECTRON MICROSCOPY IN PHARMACEUTICAL TECHNOLOGY

The application of SEM in the field of pharmaceutical technology is widespread. Solid starting materials for any kind of formulation can be visualized as well as powder

mixtures, granulations, pellets, tablets, coatings, spray- and freeze-dried products, microparticles, liposomes, and packaging materials. Although there are articles dealing with SEM investigations of raw materials (8–10) and some other materials, a general review on the applications of SEM in pharmaceutical technology is not available. Thus, this section attempts to fill the gap in the literature. The following examples were taken from our own experience over 13 years. They do not cover the whole field, but they have been selected to demonstrate that a lot of problems can be solved by the view through a microscope.

Fig. 15 Starches used in pharmacy. Rice starch (top), wheat starch (middle), potato starch (bottom left), and enset starch (false banana) (bottom right).

Starting Materials

Filler/binders

Filler/binders are used in direct compression of tablets. The requirements they have to fulfill are summarized by Khan and Rhodes (11). An important factor in the evaluation of filler/binders is their so-called “dilution

potential,” i.e., giving an amount of active ingredient that can be taken up by the filler/binder to produce a tablet according to previously fixed specifications.

Filler/binders belong to the following classes of substances: microcrystalline and powdered celluloses, lactoses, phosphates, particularly calcium phosphates, sugar alcohols, and the so-called “co-processed materials,”

Fig. 16 Disintegrants. Primojel (top left), Explotab, both sodium starch glycolates (top right), cross-linked carboxymethyl cellulose (middle), and calcium carboxymethyl cellulose (bottom).

which are especially designed combinations for direct compression (12). The following figures (Figs. 8–13) show filler/binders at different magnifications. Figure 8 (top) depicts microcrystalline cellulose (Vitacel). The fibrous structure is typical for all products of this type and differs significantly from the calcium phosphates shown below. The dicalcium phosphate dihydrate (Bekapress D2) in the middle is composed of small agglomerates, whereas

the anhydrous type (Dicaphos AN) is agglomerated to a higher extent. In Fig. 9 two types of tricalcium phosphates are presented. Crystallographically both are hydroxyapatites. Tricaphos (top) is a spray-dried product showing typically rounded particles built from very small crystallites, whereas Tritab is a granulation prepared by roller compaction (bottom). For detailed description of calcium phosphates see the relevant literature (13–16).

Fig. 17 Lubricants. Magnesium stearate (top), calcium arachinate (middle), and talc (bottom).

Fig. 18 Partially interactive powder mixture between sodium chloride (top) and micronized etilefrine HCl. The bottom picture is an extension of the middle. Etilefrine HCl settle at crystal irregularities of the cubic sodium chloride.

Figure 10 presents three different types of lactoses. The typically wedge-shaped α -lactose monohydrate (top) differs significantly from the roller dried β -lactose (middle), and the ball-shaped, spray-dried lactose (bottom), which shows the highest compactability due to

Fig. 19 Interactive mixture between lactose (top) and micronized etilefrine HCl. The bottom picture is an extension from the middle. Due to more crystal irregularities, there is a higher adherence of the etilefrine HCl onto the carrier.

its agglomerated form and its content of 8–15% of amorphous lactose (17).

The sugar alcohols, mannitol and sorbitol are quite often used in the preparation of buccal and sublingual tablets as well as lozenges. Fig. 11 shows the morpho-

logical differences between a crystallized (top) and a spray-dried mannitol (middle). Sorbitol, of which the γ -polymorph is used in direct compression, has to be regarded as the “chameleon” of tablet excipients. The spray-dried instant product (Fig. 11, bottom) is of irregular shape and shows fine needles on higher magnification. A product obtained from a melt (Fig. 12, top left) has a more regular surface as well as products that have been produced by crystallization (top right and bottom left). At higher magnifications the latter product exhibits a completely different structure compared to spray-dried sorbitol (18–20).

Figure 13 depicts the SEM pictures of three different co-processed materials (21). Ludipress, being mostly α -lactose monohydrate, shows fairly round agglomerates,

Cellactose, containing 25% of a powdered cellulose, is composed of lactose agglomerates from which the incorporated cellulose fibers protrude like tentacles. Avicel PH 200, a pure microcrystalline cellulose is an agglomerated irregular-shaped product (22).

The compressional properties of these materials with respect to hardness are similar, whereas the disintegration time shows for Cellactose a tremendous increase at compressional pressures above 100 MPa as shown in Fig. 14 (23).

Disintegrants

Starches are used as disintegrants in tablets, as binders after gelatinization in granulations, as carriers in spray drying, and as fillers and moisture absorbers in external

Fig. 20 Interactive mixtures with sorbitol as a carrier. Sorbitol plus 16% micronized etilefrine HCl, part of the granule (top left), sectional view from left showing the fine sorbitol needles and the micronized particles of etilefrine (top right). Pure sorbitol instant (bottom left), sorbitol plus 16% propranolol (bottom right).

powders. As disintegrants they are used in quite high concentrations ranging from 10 to 15% of a tablet formulation. Figure 15 presents rice (top) and wheat (middle) starches in two different magnifications. On the bottom left potato starch (one of the most commonly used starches) is shown together with starch from an Ethiopian plant called Enset false banana (*Ensete ventricosum*) showing particles of a very distinctive shape having a similar size as potato starch (24).

Besides starches, starch derivatives like sodium starch glycolate (Primojel, Explotab) are used as disintegrants as they exhibit enhanced disintegrating power. Although both products (Primojel and Explotab) are chemically identical, their microscopic behavior is different (Fig. 16, top). Primojel has a smooth surface and Explotab has a rough surface, resulting from their preparation methods that attribute to the differences in their disintegrating action (25).

Derivatives of celluloses like Ac-di-Sol and E.C.G. 505 act as the so-called “super disintegrants” (26, 27). Their microscopic pictures are similar to cellulose fibers. The

materials, however, could not be distinguished by microscopic examination.

Lubricants

Among lubricants, magnesium stearate is the most widely used one. It appears in different crystal forms, shows different particle size and shape, and occurs in several hydrate forms (28, 29). Its lubricating effectiveness was described by Delacourte et al. (30). The platelet form (Fig. 17) seems to have some advantages. Magnesium stearate is capable of forming films on other tablet excipients during prolonged mixing, leading to a prolonged drug liberation time (31), a decrease in hardness, and an increase in disintegration time (32, 33). For comparison reasons, calcium arachinate and talc are presented in Fig. 17. Calcium arachinate differs from the others by showing a microparticle structure instead of platelets.

The lubricating ability of talc is less compared with magnesium stearate, although both substances are microscopically similar (34).

Fig. 21 Dry syrup preparations. Powder mixture (top left), partially granulated product (top right), granulated product (bottom left), and coated crystals, partially agglomerated (bottom right).

Powder Mixtures

Powder mixtures could be random (35–39) or “ordered” mixtures (40). The latter were later on called “interactive” mixtures (41) due to the fact that they are not of a higher degree of order. The mixing homogeneity of an interactive mixture is not better compared with a random one, but it leads to an interaction between a fine component and a coarse carrier and then to a higher stability of the system. Pharmaceutical powder mixtures are quite often between a random and an interactive mixture, and hence they are partially interactive. The degree of interaction depends on the following parameters:

1. particle size of the “adherent” fine powder;
2. particle size and surface structure of the coarse carrier;
3. cohesion forces between the “fines”;
4. adhesion forces between the “fines” and the coarse carrier particles; and
5. relation between the amount of “fines” and coarse particles.

The following examples deal with interactive powder mixtures (42, 43). Figure 18 shows on top a sodium chloride crystal. When mixing the sodium chloride with 16% of a micronized etilefrine HCl, a partially interactive powder mixture results (Fig. 18, middle and bottom). The micronized active ingredient is preferentially adhered onto crystal irregularities. In these regions multilayers of etilefrine HCl are obtained. When choosing lactose as a carrier instead of sodium chloride, the situation changes (Fig. 19). Due to the more irregular crystals, there is a higher degree of visible adhering particles (middle). The extension of this figure (bottom) shows again the concentration of fines at crystal irregularities. Special effects could be achieved when using sorbitol instant as a carrier. Sorbitol instant is produced by spray drying and subsequent instantization. Fig. 20 presents such a particle showing an irregular shape and a rough surface. Mixing this product with 16% of etilefrine HCL (top left) results in an adherence tendency to the “valleys” of the sorbitol particle. The extension (top right) shows the fibrous structure of the spray-dried sorbitol and the micronized particles. When using 16% of micronized propranolol HCl instead of etilefrine as the active ingredient being mixed, a total coverage of the sorbitol particle is obtained. Since propranolol has a higher adhesion and cohesion tendency, after filling up the sorbitol “valleys” it covers the whole surface.

Dry Syrup Preparations

Dry syrup preparations are powdered or granular formulations prepared for reconstitution. They are filled

up to volume by a liquid, normally water, just before use. During production and storage they are solids and during administration they are either solutions or suspensions. The main reason for the development of dry syrups is the instability of the active ingredient in the liquid state. They

have to be used within a limited period of time after conversion into a suspension or solution. Most of the medicaments formulated as dry syrups belong to the group of antibiotics. It was shown that the bioavailability of a dry syrup could be superior compared with an oily

suspension (44). In addition to the active ingredient, the formulations (45) contain carriers like saccharose, sorbitol, and xylitol, acting also as sweeteners, microcrystalline cellulose and starch, viscosity enhancers, mainly xanthan gum, artificial sweeteners, preservatives,

Fig. 24 Differences in the deformation behavior of substances during tableting demonstrated by sorbitol instant as an example for a plastically deforming substance and ascorbic acid as a more brittle one. A cracked ascorbic acid crystal in a sorbitol matrix (bottom).

wetting and complexing agents, and buffer substances. They could be prepared as powder mixtures, completely or partially granulated products, and as coated coarse carriers. Fig. 21 (top left) shows as an example for a powder mix, amoxicilline trihydrate, and clavunlinic acid containing preparation. A lot of small particles of different size and shape indicate a mixture. A partially

granulated product containing cefixim trihydrate is shown on top right. Besides small size particles granules are visible. A granulated dry syrup prepared from acetylcysteine is presented on bottom left, while coated carriers that are partially agglomerated containing bromhexine hydrochloride and cefaclor monohydrate are shown on bottom right. In three of the four formulations

mentioned above xanthan gum is used as viscosity enhancing agent.

Pellets

Pellets are mainly prepared by four different methods: powder layering, rotating fluidized bed, extrusion/spheronization, and the agglomeration method. The oldest one is the so-called, "powder layering method" (46), where seed crystals in a drum are moistened by a binder solution and subsequently dusted by a fine powder. After a drying phase, the next moistening step is carried out followed by a powder application and so on. These types of pellets are characterized by

a core corresponding to the seed crystal, surrounded by fine particles. Figure 22 (top) represents such a pellet.

Pellets prepared by extrusion/spheronization (47) have uniform cross-sectional area (Fig. 22, middle) but differ slightly in shape and size, which is based on the spheronization process following extrusion (Fig. 22, bottom). They are harder compared with pellets produced by powder layering. Their appearance is similar to pellets obtained by fluidized-bed granulation using the so-called "rotating fluidized-bed" (48). Due to the fact that ideally round pellets are desired, several attempts were made to quantify their roundness (49, 50). The spherical agglomeration is a completely different method that is

Fig. 26 Differences observed in the mechanism of film formation from latex and pseudolatex dispersions-and from micronized coating materials.

employed to develop pellets that are round and uniform in size. In this, particles are agglomerated in suspension (51, 52).

The resulting pellets are round and uniform in size (Fig. 23, top left); the shape of an ascorbic acid pellet prepared from a fine powder having a mean diameter of $3.0\text{ }\mu\text{m}$ is shown in Fig. 23 top right. Increasing the particle size of the starting material to a mean diameter of $8.8\text{ }\mu\text{m}$, the surface of the pellets becomes more rough (middle left). The addition of 2% of povidone during pellet preparation smoothes the surface (middle right). A finer starting material of $3\text{ }\mu\text{m}$ leads to a smoother surface (bottom left) that could become very smooth by the addition of 2% of povidone (bottom right). This example clearly demonstrates that by spherical agglomeration, it is possible to adapt the surface of the pellets being produced by a proper choice of the particle size of the starting material as well as by the addition of a polymer (53).

Tablets

SEM was widely used to investigate the structure of tablets. An excellent review is presented by Hess (54). Imaging of tablets is a useful tool to demonstrate differences in compression behavior of substances. Figure 24 shows an example where the plastically deforming spray-dried sorbitol instant was compressed together with the more brittle ascorbic acid in one tablet. At low compressional force of 5 kN for a 10 mm tablet, the rectangular ascorbic acid crystals as well as the partially deformed sorbitol particles are visible (top left). On top right the surfaces of two tablets compressed at 5 kN (left) and 30 kN (right) are compared. At higher compressional forces, a uniform, flat, and smooth tablet surface is formed, but within this surface a single unchanged ascorbic acid crystal could be detected. Observation of a broken tablet (Fig. 24, middle), which was prepared at a high compressional force of 30 kN, reveals that the ascorbic

Fig. 27 Influence of the type of polymer application on film properties (top and side view). HP55 (HPMCP)-coated pellet, prepared from a micronized film dispersion (top). HP55 (HPMCP)-coated pellet, prepared from an organic solution (bottom).

acid crystal is totally fixed within a matrix of plastically deformed sorbitol. Even when the crystal was partially removed from the sorbitol matrix, during the break down of the tablet, the sorbitol matrix is still intact (middle right). This is supported by the bottom picture, where an ascorbic acid crystal was cracked during the breaking of the tablet, but it is still surrounded by plastically deformed sorbitol. These findings are similar to investigations of Hess (54), who used the plastically deforming potassium chloride (Fig. 25, top). On the top right, after compressing at low compressional forces, the single potassium chloride particles are separated by dips between them, while after compressing at high forces—although the original particles are still detectable—there are no visible dips.

When compressing pellets into tablets, their deformation depends on their hardness (55). When hard pellets produced by spherical agglomeration are compressed (Fig. 25, middle), the single pellets are still visible at the surface (left) and are only partially deformed in the inner part of the tablet [right, (53)]. This is of high importance, when pellets having an enteric or a sustained-release coat are compressed with the aim not to damage the coating.

The bottom pictures of Fig. 25 show differences in the elastic recovery of substances after compression. The left picture depicts the surface of an ASA-tablet containing 10% of sodium carboxymethyl starch as a disintegrant. The plastically deforming ASA remains plain after compression, whereas the starch derivative shows elastic recovery. After moistening the surface with finger the starch derivative particles start swelling moving out of the tablet surface (54).

Coatings

Coatings are applied to solid dosage forms for several reasons: taste masking, moisture prevention, gastric resistancy, and sustained-release action being the most common ones (56). They could be handled as a solution, a latex or pseudolatex dispersion, or as a suspension containing a micronized polymer powder as the film-forming agent. The film formation is easiest from a polymer solution because single polymer molecules can interact to build the coating. Using latex or pseudo latex dispersions or even micronized polymers the situation is different as demonstrated in Fig. 26. The size of true latex particles is uniform and it is in the range of 100–200 nm. A pseudolatex shows a broader particle size distribution although the mean particle diameter could be in the same range. In contrast, the particle size of a micronized particle of a film forming agent is 10 to 30 times higher compared to a latex, which is in the range of 1 to 3 or even more

micrometers. For a complete film formation, the plasticizer has to penetrate uniformly into the polymer. This is easily achieved when a latex dispersion is used. With a pseudolatex dispersion, however, the larger particles would not be plasticized completely. With a micronized polymer, on the other hand, only the outer part of the particles will be penetrated by the plasticizer. The resulting differences are presented in Fig. 27. On top, the rough surface and cross-sectional area of a pellet coated with the micronized polymer hydroxypropyl methylcellulose (HPMCP, HP55) are shown. The cross-sectional view

Fig. 28 Cross-sectional areas of different films. Eudragit L 30 D without pigments, film thickness approx. 25 μm (top), Eudragit L 30 D film containing 50% of magnesium stearate, film thickness approx. 25 μm (middle), incomplete film formation at higher magnification, showing individual latex particles from an Eudragit L 30 D dispersion in the film (bottom).

Fig. 29 Comparison of differences in size of pigments at the same magnification. Red iron oxide (top left), titanium dioxide (top right), talc (middle left), mica (middle right), and two pearl luster pigments Iridodin 110 (bottom left) and Iridodin 100 (bottom right).

hardly allows distinction between the coat and the inner part of the particle. The thickness of the film is approximately 25 µm. The pellet shown on the bottom was coated using an organic solution of HP55 showing a smooth surface and a more uniform cross-sectional view of the film. A more detailed structure of films is depicted in Fig. 28, where the influence of composition and conditions of preparation is apparent. The top picture represents a film that is produced without pigments. The addition of 50% of magnesium stearate results in a more structured layer (middle). On the bottom of Fig. 28 the cross-sectional view of an incomplete film at a higher magnification is presented. A pigment platelet is located near the surface. The latex particles around the platelet form a film, whereas those that one in the inner part of the coat still exist as latex

Fig. 30 Liberation of theophylline from aquacoat ECD 30 coated pellets with different pigments in relation to the BET surface of the pigments.

particles in the range of 100–200 nm. Obviously the minimum film-forming temperature was not reached in this region. The pictures clearly demonstrate the differences between the various application forms of film-forming agents.

Pigments could influence the mechanical properties of a film as well as the dissolution behavior of a drug substance

from coated tablets or pellets. According to Rowe (57) different pigments should be compared on the bases of the pigment volume concentration, which takes density differences into account (Eq. 3),

$$PVC = \frac{V_P}{V_P + V_B} \quad (3)$$

Fig. 32 SEM picture showing starting materials and their corresponding spray-dried products. Before spray drying both substances show a layered crystal structure but differ significantly after the spray-drying process.

where PVC = pigment volume concentration; V_P = pigment volume; and V_B = polymer volume.

Pigments exhibit different shape and size. Figure 29 clearly demonstrates that for red iron oxide (top left) and titanium dioxide (top right) on one hand, and talc, mica (middle), and two pearl luster pigments (bottom) on the other. The primary particle size of the two metal oxide crystallites is below $1\ \mu\text{m}$. The red iron oxide is more agglomerated compared with titanium dioxide. Talc (middle left) and mica (middle right) show platelet structure with a broader particle size distribution of talc. The two pearl luster pigments, both based on mica, coated with metal oxides also show the typical platelet structure and higher particle sizes. For titanium dioxide (58) and talc (59) the influence of the amount of pigment added to the film-coating formulation on the drug dissolution was shown. Up to the critical pigment volume concentration, the permeability of the films is decreased and therefore the sustained release effect is prolonged. Above the critical concentration the permeability of the films increases due to defects in the uniform film layer caused by the pigments (60).

With pearl luster pigments, depending on their particle size and/or BET-surface, respectively, this effect could be used to control drug liberation of sustained-release preparations. Figure 30 compares the in vitro dissolution of theophylline in water after 3 and 6 h from pellets that were coated with an Aquacoat ECD 30 dispersion pigmented with 20% of different pigments based on the amount of polymer used. Sicopharm (red iron oxide) and titanium dioxide, both fine crystallites, show the highest release rates. The others having a more or less pronounced platelet structure show a decrease in drug liberation that is directly correlated to the BET-surface of the pigments (60). The reason for the reduced film permeability lies in the special structure of films containing platelet-shaped pigments. Figure 31 (left) shows a section of such a film under an angle of approximately 45° . The roof-like structure of the coating is obvious. Therefore, substances penetrating the film have to permeate around the solid platelets, which prolongs the diffusion. Path consequently, the drug liberation is delayed. During the dissolution process, the film swells due to the swelling properties of the polymer. At the end of the process a picture shown in Fig. 31 (right) is obtained. The cross-sectional area of the swollen film in this case was observed under an angle of 90° . The pigment platelets are still in their original overlapping position. The degree of swelling depends on the type of polymer used. Aquacoat ECD 30 shows only a slight effect compared with Eudragit RL 30 D and RS 30 D.

Spray-Dried Products

Spray drying is used to convert solutions, emulsions, or suspensions into powders (61). The applications in pharmaceutical technology are numerous. Raw materials are spray dried, for instance, to enhance the compressional properties of substances such as lactose (62) and tricalcium phosphate (13), to distribute a minor component like digoxin more uniformly in a matrix, and to enhance

Fig. 33 Spray-drying process of extracts with respect to the behavior of a single droplet.

their dissolution rate as described for digoxin in combination with a hydrophilic polymer (63).

Normally one would expect round- to nearly ball-shaped particles from a spray-drying process when starting from a solution or an emulsion. When using a suspension, the resulting particles could also be more or less irregular agglomerates as shown earlier for spray-dried lactose and some of the so-called “multi-purpose excipients.” But even when starting from a solution round particles may not be obtained. This is demonstrated in Fig. 32. Fumaric acid and L-leucine in their original state are both crystals compasing of thin lamellae. After spray-drying fumaric acid forms small star-like agglomerates (Fig. 32, top right), whereas L-leucine forms hollow spheres built from small and very thin platelets (Fig. 32, bottom right). These spheres have advantages as lubricants in effervescent tablets compared with a milled product because the spheres are broken during compression, forming a thin

film of small L-leucine platelets on the punches and die of a tablet press. Thus, an amount of 3.75% of spray dried L-leucine in an effervescent tablet formulation was more effective compared with 5% of the milled product (64). Spray drying of extracts is quite often used to prepare readily soluble tea preparations (65). The advantages are a quicker solubility, a uniform distribution of active ingredients, and a free-flowing, dust-free powder. The drying process of a single droplet can be schematically described as shown in Fig. 33.

In the first step, liquid droplets are formed by the nozzle of the spray dryer with the aid of a pump and compressed air or by an airless system. Due to the high temperature of the drying air, the solvent evaporates first from the outer surface of the droplet and a solid “skin” is formed around the liquid that acts as a barrier for further evaporation. As a result, the pressure within the droplet increases until the wall breaks and the solvent is blown out of the droplet. At

Fig. 34 Spray-dried plant extract solutions used to prepare readily soluble tea preparations. Fig. 35 Spray-dried extracts and pantothenate solution. Spray dried calcium pantothenate: overview (top left) and detail (top right), showing mainly particles that were damaged during preparation of the SEM sample either by the high vacuum of the SEM or by the heat created during the sputter coating process. Spray dried *Tussilago farfara* extract prepared by a system using atomizing air to form droplets and leading to small particle sizes (bottom left) and a magnification thereof (bottom right).

the end, a hollow solid particle results showing small holes, where the liquid was blown out. Depending on the excipients in the formulation particles could more or less

break down during the process. The fragments then adhere to other fragments and to the spheres. This behavior is demonstrated by Fig. 34 (top left). The extract particles on

Fig. 36 Differences between spray-dried emulsions containing essential oils and nonvolatile oils during sample preparation. The oil droplets of the volatile essential oils disappear during sample preparation under vacuum, while nonvolatile oil droplets stay permanently.

that figure originating from an airless spraying system result in particle size ranges from approximately 100 to 500 μm . Fragments adhering to other particles are present as well as agglomerates of two or three spheres. The higher magnification of one of the particles (Fig. 34, top right) shows the "blow out hole" and also adhering fragments. A higher magnification of one of the "blow out holes" (bottom left of Fig. 34) demonstrates the presence of fragments and smaller spheres within a bigger particle. In the picture, at bottom right, some of the particles show irregular surfaces. These are artifacts, which are formed during sample preparation. They are built as a result of overheating during the sputter process with gold. A similar case is demonstrated in Fig. 35 (top). Most of the spray-dried calcium pantothenate particles are collapsed due to instability of the previously formed thin walled spheres under the high vacuum of the SEM. From time to time one can observe the collapsing of the particles under the SEM.

The bottom pictures of Fig. 35 demonstrate the difference to particles mentioned before when using an air-driven nozzle instead of an airless one. The particle size range of the *Tussilago farfara* extract shown in the figure is now in the range from 1 to 20 μm . Some of them are damaged by heat during sputtering (bottom left).

At higher magnification (bottom right) one single particle of roughly 20 μm in diameter is shown containing smaller ones inside. The wall thickness is in the range of 1 μm or below. In some cases emulsions containing oil in the inner phase are submitted to spray drying. The spray-dried particles contain the small oil droplets inside as well as on the surface as schematically drawn in Fig. 36. During the sputtering process of the samples under vacuum essential oil droplets are evaporated from the surface of the spray-dried particles, whereas nonvolatile oil droplets stay on the surface and are coated by gold. The different situations are demonstrated in Fig. 37 by SEM pictures. On

top, an azulene containing spray-dried particle to which smaller ones are adhered is shown. Here, no oil droplets on the surface are visible due to the fact that azulene belongs to the group of essential oils. In the middle, the surface of a 50% vitamin E acetate containing spray-dried particle is depicted. The surface is rough and higher magnification of the same (bottom of Fig. 37) clearly demonstrates the presence of small oil droplets on the surface of the spray-dried particle.

Fig. 37 Spray-dried emulsions. Particle from an emulsion containing a volatile essential oil (azulene) (top). Particle from an emulsion containing a nonvolatile oil (vitamin E acetate) (middle and bottom).

Freeze-Dried Products

Freeze drying was first carried out in 1890 by Altman (66) but became well known through the industrial development of the process. The process is used in the food industry e.g., for the production of instant coffee, tea, and other products. In the field of pharmaceutical technology, it was for a long time restricted to only few formulations for injection containing the active ingredient in the freeze-dried state in an ampoule to be dissolved just before application. With the increasing interest in protein and peptide formulations, freeze-dried products became more important. These are discussed under “microparticles for injection” in the following section.

Fig. 38 Preparation scheme of medicaments containing-freeze dried platelets.

Instantaneously soluble freeze-dried platelets (67) became known during the last few years. They were mainly developed for people having problems of swallowing a tablet. Their production scheme is presented in Fig. 38. A solution containing the active ingredient together with excipients like mannitol and if necessary polymers, sweeteners, colors, and flavors is dosed by a pump into preformed blisters of PVC or a

Fig. 39 Instantaneously soluble freeze-dried medicament platelets/tablets. Cross-sectional side view and top view (top), border line between the surface (upper part), and the cross-section (lower part of the picture) (middle), inner part of the platelet (bottom).

combination of PVC and PVDC. The blisters containing the solution are freeze dried and an aluminum foil covering the blister is applied at the end of the process. The platelets have the size of tablets as shown on top of Fig. 39 and they adapt to the form of the blister through the freeze-drying process. The surface shows small holes from channels where water was evaporating during drying. These channels form a percolating system within the tablet (Fig. 39, middle). Their microstructure is shown on bottom of Fig. 39 indicating the loose structure of the platelets having a high internal surface. Through the channels, water is penetrating quickly into the platelet leading to a very fast dissolution.

Microparticles for Injection

During the last decade, peptides and proteins became more and more important as medicaments. Most of them are unstable in an acidic environment and in the

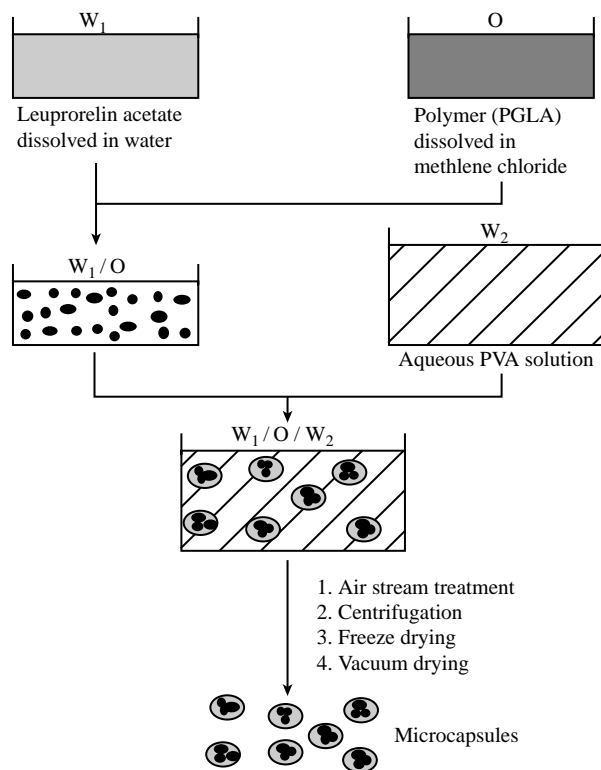

Fig. 40 Preparation of leuporelin acetate containing microcapsules according to the “in-water-drying” process.

Fig. 41 Microparticles for injection prepared by the “in-water-drying” process (top) and by freeze drying (bottom) for two LH-RH super agonists.

presence of enzymes. Therefore, they could not be administered or applied via the peroral route (68). Since the development and registration of poly-lactide-glycolides as biodegradable polymers for injectable

sustained release preparations (69), methods of preparation of injectable microparticles became very interesting. As preparation methods, spray and freeze drying and the so-called “in-water-drying” process are in use (70). The latter is demonstrated in Fig. 40. Leuporelin acetate dissolved in water and a polylactide-glycolide solution in methylene chloride are mixed forming a W/O-Emulsion, where the methylene chloride solution is the outer phase of the emulsion. By the addition of an aqueous polyvinyl alcohol (PVA) solution, a water/oil/water multiple emulsion is formed with PVA solution in the outer phase. The main part of the methylene chloride is evaporated by an air treatment leading to a precipitation of polylactide-glycolide. The resulting particles are centrifuged, freeze dried, and dried under vacuum to remove traces of methylene chloride (71). Fig. 41 shows (top) the resulting round particles as a bulk before redispersion for injection (left) and single particles at higher magnification (right). The single particle exhibit pores with small holes where the methylene chloride has evaporated. For comparison reasons, a freeze-dried product is shown on the bottom of Fig. 41.

Fig. 42 Preparation of sterile injectable implants by extrusion of a mixture of *D,L*-poly(lactide-glycolide) and an active ingredient.

Implants

Implants can be biodegradable or nonbiodegradable ones. In earlier times tablets were implanted by a small surgery and removed after a certain time period. Modern implants consist of biodegradable organic or inorganic materials. The most commonly used organic material since the introduction of Zoladex® is *d,l*-poly(lactide-glycolide) (71). The implants are cylindrical in shape and have a diameter enabling the application by syringes and injection needles. A scheme of the preparation of this type of implants is presented in Fig. 42.

The active ingredient and the polymer are mixed, extruded to a cylindrical rod, and cut into pieces of approximately 1 cm in length. These pieces are introduced into syringes and applied to the patient as an implant through a needle. Fig. 43 presents one end of the cylindrical implant at two magnifications. The higher magnification shows small irregularities at the end of the rod that could be responsible for the pain sometimes reported during the application of the systems.

A second type of implant that is used for the local antibiotic treatment of bone infections is based on β -tricalcium phosphate ceramic pellets (72). The pellets are prepared by granulation and subsequent thermal treatment between 975 and 1300°C. They are loaded with antibiotic drugs like gentamycin. The drug liberation is affected by the pore volume of the pellets leading to a sustained release of the antibiotic. Fig. 44 presents a SEM picture of some materials, showing the influence of the thermal treatment and compaction pressure of the green pellets on the structure of the material. The manufacturing data are given in Table 3.

An increase in firing temperature from 1075 to 1125°C leads to a smaller pellet and a higher density corresponding to a lower porosity. Similar compacts can be obtained at the lower firing temperature by the application of a higher compaction pressure. Hydroxyapatite shows differences compared with β -tricalcium phosphate leading to low densities at high thermal treatment. A prolonged drug liberation up to 14 days was achieved by this method.

SUMMARY

The application of secondary electron microscopy (SEM) has become widespread in pharmaceutical technology. Besides other techniques like particle size analysis, surface measurements, X-ray diffraction, and differential scanning calorimetry, it is a useful tool to

characterize raw materials. Intermediates like powder mixtures, granules, and other bulk materials could be visualized by SEM. For interactive powder mixtures it is the only method making the interaction visible. Pellets could be investigated with respect to size and shape as well as for surface characteristics and properties of coatings being applied to them. Tablets show their internal structure in SEM. Spray-dried and freeze-dried products are further interesting examples for the application of SEM. In general one could state that more than 50% of all problems could be solved by the view through a microscope.

Fig. 43 SEM picture of a Zoladex® cylindrical implant. The stripes at the lower surface result from small irregularities of the extrusion nozzle (top). ACKNOWLEDGMENTS

This chapter was written on the basis of a 13 years experience with SEM in pharmaceutical technology. The author would like to thank Mr. Klaus Weyhing for his permanent involvement in the practical work with the SEM and for his graphical support as well as Mrs. Renate Beer for typing and editing this work. Thanks should also be given to Professor Dr. Tsige Gebre-Mariam, University of Addis Ababa, for correction of the manuscript.

SEMISOLID PREPARATIONS

Guru Betageri
Sunil Prabhu

Western University of Health Sciences, Pomona, California, U.S.A.

INTRODUCTION

Pharmaceutical semisolid preparations may be defined as topical products intended for application on the skin or accessible mucous membranes to provide localized and sometimes systemic effects at the site of application. In general, semisolid dosage forms are complex formulations having complex structural elements (1). They are often composed of two phases (oil and water), one of which is a continuous (external) phase and the other a dispersed (internal) phase. The active ingredient is often dissolved in one or both phases, thus creating a three-phase system. The physical properties of the dosage form depend on various factors, including the size of the dispersed particles, the interfacial tension between the phases, the partition coefficient of the active ingredient between the phases, and the product rheology. These factors combine to determine the release characteristics of the drug as well as other characteristics such as viscosity. Although a majority of semisolid preparations contain medicinal agents for therapeutic effect, some nonmedicated semisolid preparations are used for their physical effects as protectants and lubricants. The design of a semisolid preparation is based on its ability to adhere to the surface of application for a reasonable duration before they are washed or worn off. The adhesion is brought about by a plastic rheologic behavior that allows the semisolids to retain shape and cling as a film until acted on by an outside force, whereupon they deform and flow. One can assess this behavior by thrusting a finger through the semisolid mass, which leaves a track that does not fill up when the finger is withdrawn (2, 3). Semisolids are characterized by a three-dimensional structure that is sufficient to impart solid-like character to the undisturbed system but that is easily broken down and realigned under an applied force. In broad terms, semisolid preparations may be classified as ointments, creams, pastes, and gels.

Ointments are composed mostly of fluid hydrocarbons meshed in a matrix of higher melting solid hydrocarbons. Common examples of ointment bases include mineral oil, petrolatum, and polyethylene glycol. Creams are semisolid emulsion systems with an opaque appearance. Their

consistency and rheologic properties are based on whether the emulsion is o/w or w/o and on the nature of the solid in the internal phase. Pastes are basically ointments into which a high percentage of insoluble solids has been added. Powders such as zinc oxide, titanium dioxide, starch, and kaolin are incorporated in high concentrations into a preferably lipophilic greasy vehicle to form a paste-like mass. Gels are semisolid systems in which a liquid phase is constrained within a three-dimensional polymeric matrix in which a high degree of physical cross-linking has been introduced. Most of the semisolid preparations are applied to the skin for topical relief of dermatologic conditions, whereas a lesser portion of these preparations are applied to mucous membranes such as rectal and buccal tissue, vaginal mucosa, urethral membrane, external ear lining, nasal mucosa, and cornea. Whereas normal skin permeation is limited to localized effects, the mucous membranes permit more ready access to systemic circulation. Overall, even though the nature of the underlying structures differ remarkably across all the different semisolid systems, they all share the property that their structures are easily broken down, rearranged, and reformed.

OINTMENTS AND CREAMS

Ointments utilize certain bases that act as vehicles to deliver the drug and to impart emollient and lubricant properties to the preparation. Usually, but not always, they contain medicinal substances (4). Properties of ointments may vary from product to product depending on their specific use, ease, and extent of application. In general, ointment bases may be classified into four general groups: hydrocarbon, absorption, water-removable, and water-soluble bases.

Hydrocarbon Bases

Also known as oleaginous bases, the hydrocarbon bases are essentially water-free, incorporating aqueous preparations

only in small amounts and with considerable difficulty. The primary features of this type of base include its emollient effect, retention on the skin for prolonged periods, prevention of escape of moisture from the skin to the atmosphere, and difficulty in washing off. They act as occlusive dressings, thus increasing skin hydration by reducing the rate of loss of surface water. Also, they do not dry out or change noticeably on aging. Hydrocarbon-based semisolids comprise fluid hydrocarbons C₁₆ to C₃₀ straight chain and branched, entrapped in a fine crystalline matrix of yet higher-molecular-weight solid hydrocarbons. The high-molecular-weight fraction precipitates out substantially above room temperature, forming interlocking crystallites (5). The extent and specific nature of this structure determine the stiffness of the ointment. In general, hydrocarbon-based ointments liquefy on heating because the crystallites melt. Moreover, when cooled very slowly, they assume fluidity much greater than when rapidly cooled because slow cooling leads to fewer and larger crystallites and, therefore, less total structure.

Common examples of these bases include:

1. *Petrolatum, USP*—a mixture of semisolid hydrocarbons obtained from petroleum. It is an unctuous mass, varying in color from yellowish to light amber. It melts at temperatures between 38 and 60°C and may be used alone or in combination with other agents as an ointment base. Petrolatum of varying melting ranges and consistencies are commercially available as given in Table 1.
2. *White petrolatum, USP*—a petrolatum that has been decolorized, either partially or wholly. It is used for the same purpose as petrolatum but is more esthetically acceptable to a patient than petrolatum because of its lighter color. White petrolatum is particularly useful to treat diaper rash (impervious to

urine and protects the baby’s skin) and dry skin (helps the skin retain moisture). Example 1 illustrates an ointment preparation that incorporates 95% white petrolatum resulting in an ointment base with firm consistency.

3. *Yellow ointment, USP*—the purified wax obtained from the honeycomb of the bee. It contains 5% yellow wax and 95% petrolatum in the formulation.
4. *Mineral oil*—a mixture of liquid hydrocarbons obtained from petroleum. These are useful as levigating agents to wet and incorporate solid substances (e.g., salicylic acid, zinc oxide) into the preparation of ointments that consist of oleaginous bases as their vehicle. There are two types of mineral oils listed in the *U.S. Pharmacopeia/National Formulary* (USP/NF). Mineral oil USP is also called heavy mineral oil with a specific gravity between 0.845 and 0.905 and a viscosity of not less 34.5 cSt (cSt = mm²/s) at 40°C. Light mineral oil, NF has a specific gravity between 0.818 and 0.880 and a viscosity of not more than 33.5 cSt. Table 2 lists the commercially available mineral oil fractions.

Blending of increasing quantities of mineral oil with petrolatum can produce ointments of various consistencies as desired. For example, blending 10% w/w mineral oil with 90% w/w white petrolatum base can produce an ointment with less drag or resistance to spreading, making it ideal for application to burns or other painful areas. As illustrated in Example 2, melting the petrolatum and mineral oil together and allowing them to cool forms a soft base or vehicle. By increasing the quantity of the mineral oil in the mixture, a base is

Table 1 Specifications of a range of petrolatum^a

	Melting point °F (°C)	USP or ASTM consistency	Sabolt viscosity at 210°F	Typical congealing point °F (°C)
White petrolatum, USP	122/135 (50–57)	175/205	64/75	125 (51.6)
	118/130 (47–54)	210/240	57/70	120 (48.8)
	130/140 (54–60)	155/190	60/70	130 (54.4)
Yellow petrolatum, USP	118/130 (47–54)	210/240	57/70	118 (47.7)
	122/135 (50–57)	175/205	57/70	123 (50.5)

^aWitco Chemical Corporation, Greenwich, CT.

Table 2 Specifications of a range of mineral oils^a

Type	Viscosity, cSt at 40°C	Specific gravity at 60°C
Mineral oil, USP	65.8/71.0	0.870/0.887
	72.0/79.5	0.864/0.878
	60.0/63.3	0.863/0.883
	38.4/41.5	0.859/0.882
	34.9/37.3	0.858/0.882
Light mineral oil, NF	28.1/30.3	0.856/0.882
	24.2/26.3	0.854/0.873
	17.7/20.2	0.842/0.870
	14.2/17.0	0.845/0.860
	7.6/8.7	0.831/0.842

^aPenzoil Products Company, Karns City, PA.

obtained that has a gel-like consistency indicating a more viscous preparation (Example 3). Hydrocarbon vehicles have several advantages, such as stability and emolliency; however, they suffer from one major disadvantage—greasiness—which may stain clothing and is usually difficult to remove (6).

Ophthalmic Ointments

Ophthalmic ointments differ from conventional ointments in that they must be sterile. Although the USP does not specify any particular base in the ophthalmic drug monographs, it states that the ingredients used must be sterilized under rigid aseptic conditions and again in its final container (7). In choosing an ointment base for an ophthalmic preparation, it must meet several qualities such as having the ability to diffuse the medication throughout the secretions bathing the eye, being nonirritating to the eye, and having the ability to diffuse the medication throughout the secretions bathing the eye. It must also have a softening point close to body temperature, both for patient comfort and for drug release. To avoid the risk of damage to the eye, it is imperative that the ointment be free of large particles and any metal particles. Mixtures of mineral oil and white petrolatum are commonly used as the base in medicated and nonmedicated (lubricating) ophthalmic ointments. Usually, the medicinal agents are added to an ointment base either as a solution or as a finely micronized powder and are subjected to fine milling to render the preparation uniform and smooth. The ophthalmic ointments also must meet the USP sterility tests and the test for metal particles in ophthalmic ointments. Rendering an ophthalmic ointment sterile requires special

Example 1 White ointment, USP

White petrolatum	95 (% w/w)
White wax	5

Procedure: Melt the white wax and add the petrolatum; continue heating until a liquid melt is formed. Congeal with stirring. Heating should be gentle to avoid charring (steam is preferred), and air incorporation by too vigorous stirring is to be avoided.

Example 2 Soft petrolatum base

White petrolatum, USP	90.0 (% w/w)
Mineral oil, NF	10.0

Procedure: Melt the white petrolatum and mineral oil together and allow to cool.

Example 3 Gelled petrolatum base

White petrolatum, USP	75.0 (% w/w)
Mineral oil, NF	25.0 (% w/w)

Procedure: Melt the white petrolatum and mineral oil together and allow to cool.

aseptic techniques and processing. Each drug, along with other components, is rendered sterile separately, aseptically weighed, and incorporated in preparing a final product that meets the sterility requirement (8). This is done because of difficulty in terminal product sterilization, such as lack of penetration of steam into the ointment base and instability of components owing to high dry heating. Antimicrobial preservatives such as methylparaben (0.05%) and propylparaben (0.01%) and its combinations phenylmercuric acetate (0.0008%), chlorobutanol (0.5%), and benzalkonium chloride (0.008%) are used as needed.

Absorption Bases

Absorption bases, as such, are hydrophilic, anhydrous materials (w/o emulsions) or hydrous bases (w/o emulsions that have the ability to absorb additional water). Addition of lanolin, lanolin isolates, cholesterol, lanosterol, or acetylated sterols renders the hydrocarbon base hydrophilic. Such hydrophilic mixtures have been known as absorption bases; however, the word absorption is a misnomer. Although the bases do eventually absorb aqueous solutions to be considered w/o emulsions, they do not absorb water on contact, but after sufficient agitation

only. They are conventional ointments that contain w/o emulsifiers in appreciable quantity. A w/o emulsion is formed when an aqueous medium, perhaps containing the drug in solution, is worked into the base. Thus, these bases can be classified as: 1) those that permit the incorporation of aqueous solutions, resulting in the formation of w/o emulsions (e.g., hydrophilic petrolatum), and 2) those that are already w/o emulsions (emulsion bases) that permit the incorporation of small, additional quantities of aqueous solutions (e.g., cold cream). These bases are useful as emollients, although they do not provide the degree of occlusion as oleaginous bases. They are also used pharmaceutically to incorporate aqueous solutions of drugs (e.g., sodium sulfacetamide solution) into oleaginous bases. A typical example of an anhydrous absorption base is hydrophilic petrolatum, USP (Example 4). Here, cholesterol confers the w/o emulsion property, whereas inclusion of stearyl alcohol and white wax enhances firmness and heat stability. Diverse additives including cholesterol, lanolin (which contains cholesterol, cholesterol esters, and other emulsifiers), semisynthetic lanolin derivatives, and assorted ionic and nonionic surfactants are used to emulsify water into these systems, singularly or in combination. Lanolin is probably the best known substance for the emulsification of water in an anhydrous base. Anhydrous lanolin, USP is capable of absorbing up to 30% of its weight of water to form an emulsion. Its water-absorbing capacity is improved to 50% by the addition of cholesterol. Among the absorption bases, lanolin is the oldest and best known. However, because of its tackiness and viscous nature and reports of allergic reactions, the use of lanolin is very limited. Advents in technology have successfully produced a number of emulsifiers for w/o emulsions. Used in specific formulations, emulsifiers such as polyglyceryl esters form w/o emulsions (Example 5). Absorption bases impart excellent emolliency and a degree of occlusiveness on application. However, they are also greasy when applied and are difficult to remove. The anhydrous types of absorption

Example 4 Hydrophilic petrolatum, USP (anhydrous absorption base)

White petrolatum	86.0 (% w/w)
Cholesterol	3.0 (% w/w)
Stearyl alcohol	3.0 (% w/w)
White wax	8.0 (% w/w)

Procedure: Melt the stearyl alcohol and white wax together on a steam bath, then add the cholesterol and stir until it completely dissolves. Add the white petrolatum and mix. Remove from the bath and stir until mixture congeals.

Example 5 Water-in-oil emulsion formulation

Mineral oil	40.0 (% w/w)
White wax	6.0 (% w/w)
Polyglyceryl 5 trioleate	8.0 (% w/w)
Isopropyl palmitate	3.0 (% w/w)
Sorbitol monostearate	3.5 (% w/w)
Polysorbate 60	2.5 (% w/w)
Propylene glycol	4.0 (% w/w)
Water	33.0 (% w/w)
Preservative, q.s.	

bases can be used when the presence of water causes stability problems with specific drug substances such as antibiotics. Commercially available absorption bases include Aquaphor (Beiersdorf, Hamburg, Germany) and Polysorb (Fougera, Melville, NY). Absorption bases, either hydrous or anhydrous, are seldom used as vehicles for commercial drug products because the w/o emulsion is more difficult to handle than the more conventional o/w system, and also there is reduced patient acceptance because of greasiness.

A new group of w/o emulsifiers based on the linkage of polymethoxysiloxane chains with alkyl side chains and polyol groups has been constituted (9). These emulsifiers, known as organosilicone polymers, have the capability of producing w/o emulsions with a high water content. Although the polymethylsiloxane chains possess both hydrophilic and lipophilic properties, the alkyl side chains supply the necessary lipophilic and polyol groups to provide the hydrophilic characteristics of the emulsifier. Other examples of w/o emulsifiers include cetyl dimethicone copolymer (10), polyethylene glycol-20-com glycerides (11), and a series of caprylic-capryl stearates (12).

**Water-Removable Bases
(Water-Washable Creams)**

These are the most commonly used o/w emulsion bases that are capable of being washed from skin or clothing with water. They may contain water-soluble and -insoluble components. From a therapeutic viewpoint, they have the ability to absorb serous discharges in dermatologic conditions. The water-removable bases form a semipermeable film on the site of application after the evaporation of water. As such, the base consists of three component parts: the oil phase, the emulsifier, and the aqueous phase. The oil phase, also called the internal phase, is typically made up of the petrolatum

and/or liquid petrolatum. Other ingredients such as cetyl and stearyl alcohol may be added to make up the oil phase. A typical water-removable emulsion base is hydrophilic ointment, USP, as shown in Example 6. The stearyl alcohol serves as an adjuvant emulsifier. Petrolatum in the oil phase contributes to the water-holding ability of the overall formulation. The aqueous phase contains preservative materials, emulsifier, and humectant. Humectants are added to minimize water loss in the finished composition and to add to the overall physical product acceptability. Common examples of humectants used include glycerin, propylene glycol, and a polyethylene glycol. The aqueous phase also contains the water-soluble components of the emulsion system, together with any additional stabilizers, antioxidants, buffers, etc., that may be necessary for stability, pH control, and other considerations associated with aqueous systems. Another example of an o/w emulsion base is illustrated in Example 7 (vanishing cream). The vanishing creams are so called because on application and rubbing into the skin, there is little or no visible evidence of their presence. The addition of an emulsifying agent is critical to formulating an emulsion. Emulsifiers must meet the following criteria before incorporation:

1. be a surfactant to reduce surface tension;
2. be able to prevent coalescence by being absorbed quickly around the dispersed droplets;
3. facilitate mutual repulsion between particles by imparting an adequate electrical potential to the droplets;
4. be able to increase viscosity to ensure a semisolid system; and
5. be effective at low concentrations. Emulsifiers used in cream formulations may be classified into three different categories: anionic, cationic, and nonionic emulsifiers.

Anionic emulsifiers

The active portion of this class of emulsifiers is the anion. In general, these emulsifiers are more acid-stable and permit adjustment of the emulsion pH level to the desirable range of 4.5 and 6.5. Common examples include sodium lauryl sulfate and soaps such as triethanolamine stearate. Triethanolamine stearate is one of the most popular emulsifiers for creams and lotions in use today. It is usually prepared in situ during manufacture from stearic acid in the hot oil phase and from triethanolamine in the hot aqueous phase. The amount of triethanolamine controls the pH level of the resulting product.

Example 6 Hydrophilic ointment, USP

Stearyl alcohol	25.0 (% w/w)
White petrolatum	25.0 (% w/w)
Methylparaben	0.025 (% w/w)
Propylparaben	0.015 (% w/w)
Sodium lauryl sulfate	1.0 (% w/w)
Propylene glycol	12.0 (% w/w)
Purified water	37.0 (% w/w)

Procedure: Melt the stearyl alcohol and white petrolatum in a steam bath and warm to 75°C. Add the other ingredients previously dissolved in water and warmed to 75°C, and stir mixture until it congeals.

Example 7 Vanishing cream (cream base o/w)

<i>Oleaginous phase</i>	
Stearic acid	13.0 (% w/w)
Stearyl alcohol	1.0
Cetyl alcohol	1.0
<i>Aqueous phase</i>	
Glycerin	10.0
Methylparaben	0.1
Propylparaben	0.05
Potassium hydroxide	0.9
Purified water, q.s.	100

Procedure: Heat the oil phase and water phase to approximately 65°C. Add the oil phase slowly to the aqueous phase with stirring to form a crude emulsion. Cool to approximately 50°C and homogenize. Cool with agitation until congealed.

Cationic emulsifiers

Cationic compounds are highly surface-active but are used less frequently as emulsifiers. The cation portion of the molecule is usually a quaternary ammonium salt including a fatty acid derivative such as dilauryldimethylammonium chloride. These emulsifiers are irritating to the skin and eyes and have a considerable range of incompatibilities, including anionic materials.

Nonionic emulsifiers

This class of emulsifiers shows excellent pH and electrolyte compatibility in emulsions, owing to the fact that they do not ionize in solution. Although nonionic emulsifiers range from lipophilic to hydrophilic members, a typical emulsifier system may include a mixture of both a lipophilic and a hydrophilic member to produce a hydrophilic-lipophilic balance (HLB). As devised by Griffin (13), an HLB scale can be used to establish a range of optimum efficiency for a suitable emulsifier for a certain activity such as wetting agent,

Table 3 Activity and HLB value of emulsifiers

Activity	Assigned HLB
Antifoaming	1–3
Emulsifiers (w/o)	3–6
Wetting agents	7–9
Emulsifiers (o/w)	8–18
Solubilizers	15–20
